Unlike several of its predecessors, this monograph contains no general review. My immediate reaction to this omission was to praise the economy of the editors in not adding to the several reviews published in the last couple of years. However, a non-specialist seeking in this volume a thumbnail sketch to tRNA research will be disappointed. A short article expanding the contents of the brief preface by putting each article in its context and perhaps citing other recent reviews would have added less than one per cent to the volume's bulk and price but would have increased its value both to new workers in the field and to scientists from other specialities.

This lack is compensated to a large extent by articles which have extensive bibliographies. This is particularly true of the articles beginning each section which are written by the session chairmen at the meeting who refer to articles later in their section. The invited contributors of articles have usually endeavoured to present not only their own work but also that of other

workers in the field. As the writers are, in the main, reporting topics on which they are among the leading experts, many quite reasonably present reviews of their past few years' work interspersed with that of others. This occasionally leads to a one-sided interpretation in areas where there is currently disagreement, e.g. the structure of the *E. coli* ribosome. However, the volume is generally notable for the generosity and objectiveness of the writers in reporting views and ideas contrary to their own. These virtues are not purchased at the cost of dull uniformity. Each article retains its individuality and yet the volume forms a coherent unit.

In the absence of a moratorium, it is fortunately not possible to produce "the

definitive reference work on transfer RNA". Even the proposed numbering system of nucleosides in tRNAs (Appendix IA), so eminently reasonable a year ago, looks strangely dated in the light of the structure of the tRNAs in our own mitochondria. However, this volume is the best we can hope for — a summary of the major results of past tRNA research with hints of future solutions to outstanding problems. It should prove stimulating reading to all those working in tRNA research, and those working in other aspects of gene expression will find many articles of value. □

J. P. Goddard is a Lecturer in Biochemistry at the University of Glasgow, UK.

Unifying the forces of nature

Malcolm MacCallum

Elie Cartan and Albert Einstein: Letters on Absolute Parallelism, 1929-32. Edited by R. Debever. Translated by J. Ritter and J. Leroy. Pp. 233. (Princeton University Press: Princeton, New Jersey, and Guildford, UK, 1979.) £11.40.

I FOUND these 38 letters (and one postcard) an enjoyable and interesting read, but it is difficult to discern the intended readership, and so I do not know to whom I could recommend the book. The reader needs to be polyglot. Einstein wrote in German, Cartan in French. Both are translated, Ritter presumably translating Einstein's letters and Leroy those of Cartan. The preface and notes by the editor, the well-known Belgian relativist, Robert Debever, are, however, given only in French. The translations are passable, though Leroy's seems to show that English is not his mother tongue. The reader also needs a good knowledge of the background, and the energy to read the references, as the book is not self-contained. The editor even omits one manuscript note because a slightly modified version was published, and he gives only bibliographical details of most of the printed material the correspondents exchanged.

The letters cover three main topics. The first is the writing of a historical note on spaces with absolute parallelism which Cartan drafted in only two weeks in May 1929. It appeared, accompanying Einstein's paper on his attempt at a unified field theory using such spaces, in 1930; Einstein had formulated his ideas in ignorance of the mathematical literature. The second, covered by 26 letters between 3 December 1929 and 17 February 1930, deals with alternative systems of field equations in such spaces, and qualitative features of such systems of partial

differential equations linear in first derivatives. Cartan showed there was another set of equations with the same mathematical properties as Einstein's (involuntary character, determinacy of the Cauchy problem, and arbitrariness of initial conditions), and Einstein gave reasons for thinking them less physically satisfactory. This discussion gradually narrowed to the third subject, the question of whether one could define the 'strength' of a set of such equations by counting freely specifiable functions of r variables for every r up to some maximum. Cartan argued that only the maximal r gave a meaningful result. The two authors never agreed, even in the seven later letters exchanged in 1931 and 1932. By 1932 Einstein had abandoned distant parallelism for the Einstein-Mayer theory, and the only later outcome is the much modified idea of 'strength' used in *The Meaning of Relativity* (fifth edition, Appendix II) which Debever does not cite.

What use, then, is the book? The modern researcher, seeking a unified field theory, will find little of direct relevance to present efforts in this direction. The professional historian of science would probably prefer to consult the original manuscripts. The general reader may be put off by the effort required of him. If he is not, then he may be rewarded in several ways. There are interesting personal sidelights on the characters. The speed of the mail, and the authors' energy (especially as Einstein was 50 and Cartan 60) must be admired. There is much to learn from Einstein's attitude to physical problems and from Cartan's clear and careful mathematical expositions, and some reassurance for lesser mortals in their occasional mistakes. Principally, one can understand how two great minds worked in developing an (albeit unsuccessful) attempt at one of the greatest problems in physics, the unification of the forces of nature. □

OBITUARY

Sir Barnes Wallis — 1887-1979

I FIRST heard of Wallis in 1920, when the airship R 80, for the design of which he was responsible, began its trials. In retrospect, this was the most successful rigid airship designed in this country but the Air Staff decided that they had no use for it and it flew for the last time on 20 September 1921. As a result of this decision, Wallis was forced to leave the world of design in which he had already, at the age of 34, proved himself a master. He took up teaching in Switzerland and began his courtship of the lady who was to become his wife. In 1923 however a new association with rigid airship design began. Another remarkable man, Commander (and ultimately Sir) Dennistoun Burney, had been at work during Wallis's absence abroad, gaining support for his airship project. The result of Burney's persistence was the creation of the Airship Guarantee Company, a Vickers subsidiary headed by himself with headquarters at Howden in Yorkshire, and the renaissance of the Royal Airship Works at Cardington. Wallis became the chief designer at Howden and at Cardington the design team was led by V.C. Richmond. The Air Ministry gave the Airship Guarantee Company the task of building R 100 and the Royal Airship Works the task of building R 101.

In 1924 work began in earnest on both designs. In outline they were similar, each five times as long as its greatest diameter, with that diameter at 40% of the length from the nose. They were both to hold 5,000,000 cu.ft. of hydrogen. In 1924 there also began an absurd segregation of the two design teams. I was conscious of it almost from my first day at Cardington, in July 1924. That a tremendous competition should begin in that year was inevitable, and indeed desirable, but that each team should find itself with a boundary wall round it, and have no opportunities to compare notes and progress, was absurd and damaging: each team would have benefited by knowledge of the ideas and progress of the other. Where the blame for this situation, which rapidly developed and was sustained to the end — the end of R 101 — should lie I am uncertain. Wallis, already a successful airship designer, highly individualistic, formidable in his belief — not unjustifiable — in his own ideas, was almost the antithesis of Richmond, whose experience had been with non-rigid airships and whose merits were rather those of a manager and a talent-spotter than of an aircraft designer. Each was scornful of the other's efforts. In

Camera Press

my five years at Cardington I do not think they ever met. But the long-range animosity — it was no less — was fostered by others, and if Richmond was no genius as Wallis was, he nevertheless had an *eminence grise*, Flt Lieut. (later Sqdn Leader) F.M. Rope at his elbow whom, had Wallis ever met him, he would have had to admit to his own extraordinary intellectual level.

In R 100 Wallis, I believe for the first time, exhibited his passion for helices. The main booms of the heavy triangular section girders were made by rivetting duralumin strip on itself to produce a tube resembling a paper drinking straw. Wallis designed the special rivetting machine for the job. The wiring conveying the lift of the gasbags to the joints of the structure was a system of helices — or, more accurately, geodetics — in which the mesh became finer as the height from the bottom of the ship, and hence the gas pressure, increased. The affection for the helix, which in Wallis's hands produced elegant solutions to structural problems, manifested itself even more dramatically in his two most famous aeroplanes, the Wellesley and the Wellington.

Before the splendid flight of R 100 across the Atlantic and back in the summer of 1930, Wallis had been persuaded by Sir Robert McLean, the managing director of Vickers, to leave Howden and join the

aircraft design side of Vickers. His first appointment was at the Supermarine works at Southampton where he did not cooperate successfully with another remarkable man, R.J. Mitchell, the designer of the Spitfire. After a few months he was moved to Weybridge to work alongside still another great man, R.K. Pierson, famous for a whole series of aircraft, including the Vimy which made the first transatlantic flight in 1919. They were both ranked as Chief Designer.

The association of Pierson and Wallis was a complete success. Pierson was a big man, in physique and in character: soon Wallis, four years the elder, whom at this time I began really to know, called him Uncle Rex, which I think defined Pierson's relations with the major personality so suddenly thrown into close association with him.

While Wallis was back at Howden during the preparations for R 100's Atlantic venture, he was not allowed by McLean to fly in her, which seems a little hard. But by the time he had left Howden for Southampton, Wallis indeed had already begun to doubt the future of the airship in the face of the dramatic progress of the aeroplane, so perhaps he did not feel the deprivation too deeply. He was soon back at Weybridge thinking about aeroplanes and developing the system of geodetic construction.

At that time I was working on criteria defining the stiffness characteristics of aeroplane wings necessary for avoiding wing flutter and loss of aileron control due to wing twisting. Wallis came to see me and said, in effect, "Tell me how stiff to make my Wellesley wing and I will make it that stiff and no more". I told him and he did indeed achieve the minima I prescribed with a structure which was extremely light. The structure weight he achieved was well below what was being achieved in wings of more conventional construction.

I have never been convinced that Wallis's geodetic system was intrinsically superior to more conventional systems. It was superior in practice because he designed extremely efficiently to the prescribed limits. I have no recollection of any other designer of those days seeking at the outset of his design to discover the stiffness limits to which he should design. Even if I do dare to doubt the intrinsic superiority of geodetic construction however, I certainly do not deny its elegance. It had moreover a tremendous advantage in battle. The fact that strength and stiffness were, so to speak, distributed in what was almost a skin of geodesic mesh meant that the structure had few weak points, and gunfire from the ground and from the air might knock great holes in the structure without wrecking it. So triumphant was it that one might well ask why it did not persist as a basic system for aircraft construction. The answer is that the whole trend of design was away from frameworks covered with fabric and towards all metal monocoque construction. That is why the Wellesley and the Wellington were never emulated, even by Wallis himself.

The Wallis I knew was never the arrogant

prickly person we of the R 101 design team were led to visualise. Certainly his was a strong character, certainly he was firm in his views, but equally certainly he knew his limits and did not hesitate to seek help in areas beyond them — as when he sought my aid on wing stiffness — and I am sure he sought Pierson's aid, particularly on the aerodynamic side of his designs. He was indeed sometimes critical of others working in his own areas of expertise, but who is not? I always found him supremely articulate, subtly persuasive and invariably polite, all in a voice it was a pleasure to listen to. I found him, too, appreciative of the work of others. I recall that it was with some trepidation that I took him, at his request, to Hucclecote to see the drawings of the Gloster E 28/39 which Carter was designing for the first flight of the Whittle jet engine. I thought there might be questions of the "Why didn't you do it this way?" kind. There were not. Carter was completely open — he displayed all his ideas and Wallis had nothing but commendation then and afterwards.

I had no contact with Wallis on the Mohne and Eder dambusting bomb nor its massive successor. But I was in touch, as an occasional visitor to Weybridge, with his ideas on the swing wing or variable geometry aeroplane and bitterly disappointed at the lack of support for his ideas. The swing wing has been with us for some years now, but had it been adopted in practice when Wallis showed the way this country would have had a commanding technological lead in a new field: once again, we threw away a golden opportunity.

In his office on the old Brooklands track, and after his retirement from

Vickers in his home, he always worked out his ideas himself on his drawing board. Obviously, on his great projects, he directed the work of others. But the intricacies of joints in geodetic meshes, the details of the pivot of a swing wing, were elucidated on his own board. It was the same to the end: when I last saw him in his house at Effingham he was working on his board on very high speed vehicles indeed. I can only hope his efforts to bring these last visions to reality will not be wasted.

I have made no attempt in these notes to chart the long life of Barnes Neville Wallis, from his birth on 26 September 1887, to his death on 30 October 1979. The fullest account, up till 1970, is Mr Morpurgo's biography¹. I do not agree with quite all of Mr Morpurgo's judgements — nor indeed with quite all of those he attributes to Wallis — but factually it is a vivid and accurate account of a great man's life and I hope the biographer will add a chapter to complete the story. In that book we can read the true account of how Wallis was awarded by the Royal Commission on Awards to Inventors £10,000 for his dambusting bomb, and how he applied that sum to the creation of a foundation at his old school, Christ's Hospital — of which he was Treasurer from 1957 to 1970. This splendid act illumines facets of Wallis's character with which the world in which he became famous was unfamiliar — his loyalty, his generosity, indeed his unselfishness. In total he was a great and good man. We who knew him were greatly privileged.

Wolfgang Yourgrau

WOLFGANG H.J. YOURGRAU died suddenly at his home in Denver, Colorado, USA, on 18 July 1979, at the age of 70, shortly after returning home from an extended tour of lecturing and research in Europe. His passing marks the disappearance from the world of physics and the philosophy of science of a colourful scholar and humanist, whose diverse talents and activities have left enduring imprints far outside the field of his speciality.

Wolfgang Yourgrau was born on 16 November 1908 near Berlin of a Belgian father and a German-Jewish mother. He attended the Werner-Siemens Realgymnasium in Berlin and subsequently studied theoretical physics, mathematics, and biology at the local von Humboldt University, at a time when celebrated physicists such as von Laue, Einstein, and Schrödinger graced its Faculty. Serving first as a tutor in natural philosophy and then as an assistant to Schrödinger, he earned his Dr phil. *magna cum laude* in

1932, the terminal year of the Weimar Republic.

The next year saw the ascendancy to power of the Nazis, and Yourgrau, who got their attention as an organizer of the S.A.P. (an offshoot of the German Social Democratic Party), fled Germany after being severely beaten up by the Storm Troopers. In exile, he remained on the move while lecturing on the evils of fascism in Latvia, Poland, and other European countries, until he was allowed to enter Palestine, then a British mandate, as a political refugee.

Appointed a lecturer with the educational and cultural division of the *Histadrut* (Jewish Federation of Labor), he travelled widely inside Palestine and became drawn into discussions on the intractable problems of this territory. But Nazism, its devastation of the cultural values in which his family had been rooted for centuries, and then the daily progress of World War 2 remained foremost in his mind. In the Spring of 1942 he acquired from the British authorities a license to publish *Orient*, an independent German-

language weekly, with himself as Editor-in-Chief and Arnold Zweig, the renowned novelist-dramatist and a fellow exile, as co-publisher. Under Yourgrau's direction, *Orient* — which has lately become the subject of detailed analyses by some literary historians — declared war "on every fascist movement, every attempt to restrict the right to free expression of opinion . . ." But it was a subsidiary point on the programme of *Orient*, touching on the complex internal politics of Palestine, which made the journal a centre of intense controversy. Boycotts and threats against businesses connected with *Orient* and finally destruction of the premises of its fourth printer caused the financially plagued journal to close down for good in 1943, one year after its inception.

Yourgrau lost no time in assuming a more active role in the war against the Axis Powers, which was then increasingly being fought in the Mediterranean theatre. At first, working from an office of the Palestine Information Office, this only meant preparing the news bulletins in

German that emanated daily from Jerusalem Radio. But after the American Office of Strategic Services established its Middle Eastern Headquarters in Cairo, Yourgrau also was recruited to serve with that organization, vitally assisting it in its planning of some intelligence operations behind enemy lines, details of which are only now being declassified.

At War's end Yourgrau redirected his phenomenal energy into the resumption of his academic career and the pursuit of his pre-empted research. He became Head of the Department of Logic and Scientific Method at the School of Higher Studies in Jerusalem and subsequently Acting Dean of its Faculty of Arts and Sciences. At the request of the Colonial Office he went to Cyprus in 1948 to determine whether a branch of the University of London should be opened on that island. ("Under no circumstances!" his report concluded after 4 months of investigation.) In the same year Yourgrau emigrated to South Africa, having previously married South African-born Thella Garber. For a decade he taught and continued his writing and research at the Universities of Cape Town, Witwatersrand, and Natal.

In 1959 he moved to the United States, first to accept the position of Research Professor at the Minnesota Centre for the Philosophy of Science, and then to become Chairman of the Department of History of Science at Smith College in Northampton, Mass. In 1963 he accepted a permanent position as Professor of History and Philosophy of Science at the University of Denver.

The scope of Yourgrau's publications was prodigious. Ranging from the political editorials in *Orient* to papers on general relativity, they made him known to an exceptionally large spectrum of scholars, a fact that is attested to by the scheduled appearance in 1981 of a memorial volume of essays in his honour written by a diverse and distinguished panel of more than 30 of his academic colleagues. Although most of his papers are devoted to problems in theoretical physics, a large fraction deals with philosophical issues, while some others treat matters of a biographical, literary, or political nature. Of the many books he co-authored or co-edited, *Variational Principles in Dynamics and Quantum Theory* and *A Treatise on Irreversible and Statistical Thermodynamics* are perhaps the best known. In 1969 he founded, with Henry Margenau of Yale University, the international journal *Foundations of Physics*, which he co-edited until his death. He was the recipient of numerous distinctions and honours, which included the Swiss Einstein Medal, awarded to him in 1970.

Gregarious and extrovert, his forthrightness and lack of false modesty endeared him to some, made enemies of others. His co-workers and many friends in different parts of the world enjoyed his unique kind of humour, were buoyed by

his passion for life, and stimulated by his enthusiasm for intellectual pursuits. Sentimental and deeply emotional, he was intensely loyal to individuals whose friendship he valued, expecting the same degree of allegiance in return. But perhaps the most enduring impression will be his automatic reflex to side with, and concretely support, human beings — whether fellow students in Germany, penniless intellectual exiles in Palestine, or anyone else who crossed his path — who were treated unjustly or were in need of help. He is survived by his wife, a daughter, and three sons, to whom we extend our profound sympathy in their great personal loss.

Alwyn van der Merwe

David Scott Gilbert

DAVID SCOTT GILBERT was born in Ithaca (N.Y.) on 6 November 1940. He majored in mathematics at Harvard University (1959-63) then, perhaps because of a biological tradition in his family, joined D.H. Fender at the California Institute of Technology, where he gained his doctorate on visual acuity and eye movements. His postdoctoral work was with the late Trevor Shaw at Queen Mary College London, where he later became a lecturer in zoology before joining, in 1973, the Medical Research Council Cell Biophysics Unit at King's College London. He died suddenly of viral pneumonitis on 11 December 1979.

While working with Shaw on sodium transport across the membranes of giant axons, Gilbert became interested in the structural properties of axoplasm and thus concerned with problems of the determination and maintenance of the shape of nerve cells. His first paper on axoplasmic structure in 1972, (*Nature, New Biology* **237**, 195-198) was remarkably stimulating and procedurally elegant. Using polarised light microscopy he showed that the giant axon of *Myxicola* (a marine fan worm) can be described in terms of three levels of helical organisation. The axoplasmic fibrous proteins are arrayed in parallel 'ripple' helices, which are twisted into a larger 'segmental' helix. They form a cylindrical gel that can coil, when the worm shortens during contraction, to form a yet larger 'gel' helix. Gilbert recognised that this axon consisted of essentially one structural component, the neurofilament, and therefore it provided an unparalleled opportunity for experimental study. The demonstration of the helical organisation led to a model in which the filamentous protein forms into twisted strands like a rope and, although the protein content of the axoplasm of *Myxicola* is no more than about 4%, the yarn gives it significant

mechanical strength and stability; and it can shear to form branches.

Many earlier observations of axons had been interpreted as demonstrating them to be a viscous soup, rather than this kind of stiff gel, and had led to the supposition that the mechanical properties were due to the membrane and associated connective tissue. Gilbert and his colleagues found the neurofilament gel to be solubilised by a very rapid enzymic autolysis triggered upon the entry of calcium ions into the axoplasm; the technique of very quickly extricating the axoplasm in air had avoided exposure to the calcium ions of physiological saline or sea water. This method enabled Gilbert (1975) unequivocally to determine many of its bulk chemical and physical properties (*J. Physiol. Lond.* **253**, 257-319). Thus the preparation provided an important standard of reference for working on the biochemistry and structure of filaments (10nm filaments, *Nature* **272**, 557-8) and formed a firm basis from which a long-needed attack on axonal structure at the molecular level could begin.

Gilbert was leading the developments on a wide experimental front at the time of his death. Fortunately much of his work with that of colleagues is drafted for publication. Using mammalian as well as cephalopod and annelid nerve cells they have uncovered a wide variety of different neurofilament proteins. To examine their homologies they have developed a new high resolution system of gel electrophoresis and are beginning to show by fingerprinting techniques that the variety of neurofilament chains in several species, including some mammals, conceals an underlying simplicity. With a view to uncovering the biochemical as well as the structural features of neurofilaments Gilbert and his colleagues have assayed their modification by the action of axonal proteases and of endogenous kinases and phosphatases. At the same time data from X-ray and solution studies are leading to the development of a detailed molecular model of the neurofilament.

Gilbert had a keen critical intelligence and an uncommon ability to choose significant and clear-cut biological problems. He mastered a wide variety of techniques and brought to them exceptional manipulative skill. In our laboratory his broad interests and strong grasp of physical principles made him much in demand for discussion and advice. He was infallibly helpful and generous. We, his colleagues, are impoverished by his death, which will grievously set back the development of this kind of neurobiology in Britain. David had an essential humility and natural friendliness that enabled him to enjoy an easy relationship with a wide variety of people. We mourn him as much because we have lost a friend, as because a young scientist of distinction has vanished from the international scene.

27 March 1980

Foreign students: time for the government to do its sums

To judge by the pattern of previous years more than 90% of all applications for university places for the next UK academic year have now been made, and it looks, at first sight, as if overseas applicants have not been substantially deterred by the government's ill-considered decision to make this year's fees two to five times higher than last year's. The acid test, however, both for universities and other institutes of further education will come after the summer when they discover the rate of conversion of applicants into real students bearing the new fees. And since the omens do not look good, the universities are gloomily pondering the likely consequences.

There was, and still is, little evidence that much thought went into the possible consequences of last November's decision to raise the fees. Rather, the decision was part of the government's sweeping monetarist policies aimed at reducing public expenditure. The facts were that in 1978 87,000 overseas students attended UK institutions of further education (35,000 at universities) and that they were being subsidised by the British taxpayer to the sum of £100 million per annum.

In order to save the taxpayer that sum it was decided to charge overseas students the full cost of their studies. That meant £3,000 per annum for undergraduate science courses and £5,000 per annum for those undertaking medical, dental or veterinary studies. The fees for postgraduates were not stipulated, but many universities have decided to use the same rates.

The universities have been warned to expect their grants to be cut in the next academic year by an amount commensurate with their past intake of foreign students. It will be up to the universities to recoup their lost income from the students. The question is: what happens if much of the income does not materialize because the universities find themselves priced out of the market? — a distinct likelihood according to recent polls of extant foreign students in the UK that have been taken both by universities and student bodies.

There are certain prestige institutions whose very existence would be immediately threatened were their intake of overseas students to drop by the 40% to 90% that some of the polls suggest. The London School of Hygiene and Tropical Medicine with 75% foreign students and the Royal Postgraduate School of Medicine with 47% foreign students are particularly vulnerable. The Imperial College of Science and Technology and the University of Manchester Institute of Science and Technology would also have serious problems.

Even a considerably smaller shortfall in foreign students than the polls suggest will have serious consequences. In the first place it will inevitably exacerbate the academic job shortage, and make yet gloomier the prospect of easing the situation, given the demographic decline in home-grown students that begins in a few years' time.

Next, a shortage of foreign postgraduate students seriously threatens the quantity of research carried out in the UK, since many a busy academic runs his or her research project with one or

more hard-working foreign graduates. And they are irreplaceable because there is neither the financial support nor the moral justification — given current career prospects — to replace foreign graduate students with more from within these shores.

Another worrying prospect about the increase in fees is that it will not just deprive foreign students of an education in the UK, but that it will altogether hinder their chances of overseas studies. In particular, the many students from developing countries that were once British colonies who have taken advantage of the subsidised rates on offer in the UK may neither be able to afford the new fees nor to find the places or the cash to study elsewhere overseas. That would be not just a blow to the individuals and their countries of origin, but would also decrease UK influence in worldwide scientific and educational matters.

For the present, the government is adopting a policy of wait-and-see, possibly because it is not particularly concerned about the outcome either way. Thus, if it turns out that the new fees can be afforded by the majority of students, no harm will have been done. Whereas any substantial drop in student numbers can be used to justify a retrenchment of the funding of further education, a welcome opportunity for a government intent on cutting public expenditure. Presumably the government does anticipate a drop in overseas student numbers, because it has repeatedly emphasized that their number has almost trebled in the past decade, and that it currently exceeds by 15,000 the nominal quota set by the previous government. It has also argued that many of the current overseas students come from wealthy oil-producing countries well able to afford the new fees — an argument that ignores the plight of those who cannot and the fact that universities estimate that no more than ten per cent of their foreign students come from the wealthier nations.

The only concession so far made by the architects of the new policy is to provide the Committee of Vice Chancellors and Principals with enough money to provide bursaries covering the increase in fees to the 400 most able postgraduate students. Even that small but welcome concession is likely to be more than wiped out by the effects of last summer's 15% cut in the budget of the Overseas Development Administration which, in 1978, had supported in part or in whole more than 9,000 students from developing countries pursuing academic qualifications in the UK.

In the circumstances, what is urgently needed is some real idea of government thinking on the consequences of its policy. At present, even the very genuine concerns of such threatened centres as the Royal Postgraduate Medical School have been met with a stony wait-and-see response from the government, who could surely provide some concrete reassurance about their survival in the event of a serious loss of foreign students. In any case, faced with the contradictory evidence of the number of applications and the polls of students already here, it is surely time for the government to devise and carry out some real investigation of the rate at which foreign students will appear next academic year. □

United States

Research data: private property or public good?

Do scientists have a right to protect preliminary research findings from outside scrutiny? **David Dickson** reports on a growing controversy

LAST year, when a New York public interest group needed help in analysing the results of a national survey of infant-feeding practices, it turned to the Center for Disease Control (CDC) in Atlanta for assistance in putting the data through a computer.

CDC agreed to cooperate, and the data were duly stored. But being a public agency, its records are open to public scrutiny under the Freedom of Information Act. And CDC subsequently received a request from Abbott Laboratories and Mead-Johnson (a subsidiary of Bristol Myers), for access to the survey data. Ross Laboratories (a subsidiary of Abbott) and Mead-Johnson have been criticised over the nutritional value of their baby foods.

In January an administrative law judge upheld CDC's view that it lacks the legal power to deny the companies access to the data. And the centre is now being taken to court by the public interest group, the Interfaith Center on Corporate Responsibility (ICCR) to protect its data until it has been able to analyse the results and publish its own conclusions.

Two factors are complicating the increasingly sensitive problem of whether a research worker has any moral or legal rights over preliminary research data. The first is the growing economic importance of such data, for example where animal studies or clinical trials determine whether a new drug can be licensed. The second is the public's demand for information on substances likely to affect lives.

In the case of privately funded research, companies retain the right to withhold all test data supporting claims of efficacy or safety, on the grounds that these are trade secrets whose publication might have an economic impact on the product.

Moreover the Supreme Court, in a case brought by a group of physicians demanding access to data criticising the efficacy of an anti-diabetes drug, ruled last month that the raw data generated by a private laboratory under contract to the National Institutes of Health do not constitute an 'agency record' within the meaning of the FoI Act.

The main problem concerns the type of access permitted to federally-conducted research: in the case of clinical trials, for example, it can be argued that the disclosure of partial results before the trial is completed may jeopardise the final outcome.

Spurred by such concerns, NIH is seeking exemption for such data from the

Freedom of Information Act. Initially it had proposed that both epidemiological studies and clinical trials should be exempt. But following various objections, it has now developed a more restricted proposal, namely that it will be possible to withhold from public disclosure 'trend data' until it has been completed and verified (individual medical records are already protected by law).

To counter the argument that, without access to information on the conduct of the trial, the public has no check on whether it is being carried out responsibly, NIH is also proposing that exemptions will only be allowed if explicit measures have been taken to assure patients' safety.

Not all critics are satisfied. Dr Sidney Wolfe of the Health Research Group for example, which has consistently attacked the secrecy surrounding drug tests, argues that the protection of patients and the integrity of the tests can only be guaranteed through the fullest possible disclosure.

"Research workers can have an incredible bias, which may not be in the best interests of participants or intended participants in a particular trial" he says. "In general the more people who have access to a given body of data, the better".

Others argue differently, not only supporting the pragmatic claim that up-setting a large-scale blind trial may be very expensive, but also suggesting that a research worker has a moral right to present the first interpretation of data he or she has collected.

"This has been an underlying postulate of scientific conduct which is generally accepted" says Professor John Edsall of Harvard University, chairman of the

American Association for the Advancement of Science's Committee on Scientific Freedom and Responsibility.

Some also fear that, if a scientist's research notes are not protected from public scrutiny, he or she may be tempted to destroy them once the data has appeared in its final form.

The NIH's proposal that its clinical trials may, in given circumstances, be exempt from the full provisions of the FoI Act have been closely scrutinised by the NIH's Ethics Advisory Board. And following lengthy discussion of the revised proposal at a meeting of the board two weeks ago, it seems that the board will be prepared to support the proposal when it meets again in April.

It has been less convinced by arguments that information provided by private hospitals to CDC — for example on problems of infection in hospital wards — be kept secret for fear that publicity could generate undue public concern.

CDC had argued that, without some guarantee of anonymity, hospitals may be reluctant to come to them for assistance. But board members expressed the opinion that, although exemptions might be appropriate in some circumstances, this type of information was likely to have already reached the public domain by other routes.

And then there is the case of the infant feeding survey results, private data whose presence in CDC's computers appears to have made it public.

Here the view that all information should be as open as possible conflicts directly with the claim that, particularly in such a sensitive area, those who have collected the data should be allowed to offer their interpretation before others try to refute it.

Indeed, in this case the two baby-food manufacturers concerned have already written to family practitioners suggesting weaknesses in the study, which was carried out to discover the extent to which lower-income families use processed baby foods, and the nutritional implications.

ICCR claims that, since it collected the data — and has agreed eventually to make it available to anyone interested — it has a right to prevent its prior use by others. And it quotes in support the practice of the World Health Organisation, namely that research data received for analysis and processing "will not be released in incomplete form to any third party without permission from the research scientist who has collected the data".

It is now up to a court of law to decide what force the traditions of the research community hold against current legal definitions of the rights of access to the results of research. □

"What makes you think the computer will be biased against processed baby foods?"

US universities are keeping pressure on federal agencies to reduce the burden of government regulation on the administration of research grants. The universities claim that over-zealous regulation has created a climate of distrust between themselves and the government.

Two reports emphasising the need for more sympathetic regulation have recently appeared in Washington, one arguing for a general relaxation of the rules governing how universities should account for the use of research funds. The other seeking institutional changes in the way that such rules are administered.

The first report, produced by the National Commission on Research, a body established in 1978 by a group of higher education institutions, says that universities should be given greater responsibility to regulate themselves. For example, rather than research workers being required to complete detailed reports of the way in which they spend their time, it suggests that there should be merely "explicit certification by individual investigators that direct salary charges to their research agreements are reasonable and fair, coupled with the federal program officer's review of the reasonableness of these expenditures for the work undertaken".

The commission, whose report appears in the 14 March issue of *Science*, also recommends that government agencies and universities should construct an option, analogous to the "standard deduction" in income tax calculations, to charge activity treated as indirect costs under sponsored agreements. The fixed percentage would be

Grants regulation: change urged

negotiated, and could either be uniform, or vary from one institution to the other.

More specific recommendations have come from the Sloan Commission on Government and Higher Education, a two-year enquiry financed by the Alfred P Sloan Foundation of New York. In general, says the Sloan Commission, support systems for university research are "fundamentally sound". But steadier funding and long-term real growth are needed: and like the NCR, the Sloan Commission criticises the excess of government regulation.

The Sloan report, which was published in Washington last week, recommends the development of a "corps of federal auditors sophisticated about scientific research and how research universities operate". It suggests that the "natural location" for a new audit agency would be in the National Science Foundation.

At present, most universities are audited by the Department of Health, Education and Welfare, according to a federal rule that auditing responsibility is assumed by the government agency which provides the largest financial support.

In recent months DHEW auditors have become increasingly critical of the way in which universities account for the use of research funds, pinpointing areas of

misuse and inadequate auditing. According to the Sloan Commission, however, DHEW's representatives "often have little experience in dealing with research institutions, receive little training, and typically stay in the assignment only briefly".

The commission suggests that the NSF is the most competent body to conduct financial oversight since it is "the only federal agency devoted entirely to research". (Although others have argued that its present close relationship to universities might preclude any credibility as an objective auditing agency.)

In other recommendations designed to strengthen federal support of university research, the commission recommends that every research grant and contract carry with it an additional 7% of the project's direct costs. These would be used in direct support of research, but on projects selected by the university and its faculty rather than the funding agency.

And in order to help alleviate the growing problem of faculty recruitment, the Sloan Commission recommends that about \$100 million a year be spent on two new kinds of fellowship to provide short-term support for PhDs. One would be a scheme of 1000 competitive national post-doctoral fellowships awarded each year, and carrying two years' support, and renewable for a further two years. The second would be a scheme of 300 national research fellowships, each carrying five years of support for research on university campuses, in federally-funded research centres and intramural federal laboratories. □

Antibiotics in animal feeds: health study 'may be impossible'

In a report that gives little direct guidance to policy-makers, a panel of the National Academy of Sciences has concluded that there is insufficient evidence to determine whether the use of sub-therapeutic doses of antibiotics in animal feeds is a significant threat to human health.

The report also states that the research necessary to establish and measure a definite risk "has not been conducted and, indeed, may not be possible."

The Academy's report seems likely to spark another round of a controversy that has simmered ever since the publication of the Swann report in the UK in 1968. This pointed to the dangers of antibiotic resistance being passed from animals to humans. Antibiotics in animal feedstuffs were subsequently banned in the UK, and later in other European countries.

Attempts to impose a similar ban in the US have been strongly opposed by the animal feedstuff and livestock industries. When the FDA announced in 1977 that it was considering such a ban, the proposal was withdrawn after a public hearing at which several companies expressed the view that there was insufficient evidence to demonstrate that such a ban was necessary

— and that if imposed it would considerably increase the price of meat.

The Academy's report, produced by a panel under the chairmanship of Dr Reuel Stallones of the University of Texas School of Public Health, provides little clue to the FDA about how it should proceed. But it does highlight areas in which more data are needed.

For example, the report says that those in close contact with animals receiving antibiotics "are more likely to harbour antimicrobial resistant *E. coli* than persons who are not exposed. However, studies do not usually indicate the type, duration and dose levels of the antimicrobials received by the animals: sub-therapeutic use was not distinguishable from therapeutic use".

Furthermore, the panel states, there are no data from which to assess the relationship between the consumption of meat from animals that received sub-therapeutic amounts of antibiotics, and the general prevalence of antimicrobial-resistant *E. coli* in human populations.

Nor, it suggests, can much help be gathered from studying the situation in Europe. "Data gathered from the United Kingdom, the Federal Republic of

Germany and the Netherlands do not indicate clearly whether restrictive regulations have actually reduced or averted the postulated hazards to human health", the report says.

And it adds that restrictions on the use of antibiotics in the United Kingdom "may well have altered the patterns of their use without significant alteration to the total amounts used or their consequences".

The committee does suggest four possible studies on individual aspects of the transmission chain — on the effects in animals, on the passage of antibiotic resistance to meat-eaters, on the effects of occupational exposures to animals, and on the human morbidity and mortality consequences of antibiotic resistance — which, it says, "would provide a useful scientific background for policy-makers".

But the panel warns that at best "the remaining gaps in our knowledge will still have to be bridged by conjecture and speculation". This is little consolation to the FDA or to Congress, which has already provided a further \$1.5 million in the Agency's current budget for a full-scale comprehensive survey.

Soviet Union

Incident at Military Village No. 19

LAST week the Soviet Union for the first time admitted that an outbreak of some killer infection occurred last year in Sverdlovsk. Replying to a question from the US State Department, the Soviet authorities confirmed that an outbreak of anthrax did occur, but maintained that the disease was caused by poor food handling, not by bacteriological warfare agents as rumoured in the West. Since the Soviet Union has signed the international convention banning the use of such agents, this denial comes as no surprise. What is perhaps most significant is that the Soviet authorities have admitted that some bacteriological incident did take place after almost a year of "no comment" or "nothing happened".

Sverdlovsk, on the eastern side of the Urals, is a "closed city" to which foreign visitors are not admitted. Local information reaching the West is necessarily at least second-hand, and it would be unwise to give undue credence to every detail. The details on which the US State Department based its enquiry seem to be drawn from a single Russian underground source — albeit one which claims to emanate from Sverdlovsk.

However, even one such document is worth taking seriously — if not as evidence of what occurred, at least as a pointer to local fears and responses.

According to this document, in April 1979 there was an escape of a bacterial strain called V-21 in "Military Village No. 19" on the south-western outskirts of the city. The bacteria were carried by a north wind to the village of Kashino, with only a negligible amount reaching Sverdlovsk proper.

Casualties were mainly among the military and civilian residents of "Military Village No. 19", inhabitants of Kashino, and workers at the local ceramics plant. Death typically occurred some 1-3 hours after hospitalisation, following a fever of over 42°C. Special army nurses wearing protective clothing were brought in. Bodies of those who died were not returned to the relatives for funeral ceremonies. The total death toll was unofficially estimated at over 1,000.

Official local reaction, says the report, took the form of placebo messages, which gradually escalated from "nothing is happening" at the beginning of the outbreak, to "nothing happened, and anyway, don't panic, it is all localised and under control" towards the end. Finally, the streets of Kashino village were paved with asphalt, apparently to neutralise remaining infection.

Equally circumstantial are rumours emanating from Slovakia of a similar incident involving a Soviet military base.

Here, however, there were no fatalities, only a widespread outbreak of what appears to be a new form of infective hepatitis. According to local sources, an area of central Slovakia some 70 km by 30 km is regularly used by Soviet paratroopers as a training ground. Some time in late August or early September it is alleged that one such training exercise led to the accidental discharge of bacteriological weapons. The military casualties were said to be too numerous for the existing army facilities, and the

overflow was taken to civilian hospitals in Poprad and Spisska Nova Ves.

Inevitably some of the virus was borne by the wind outside the training ground, and "several thousand" of the civilian population also succumbed. The Slovak sources stress that this does not appear to have been intended as a killer weapon — rather one to debilitate and incapacitate the local population and thus minimise resistance before the arrival of an unwished for "peace-keeping" force.

Nuclear energy

Loch Doon, Scotland: UKAEA refused test drilling permission

Power dissenters through Europe

AN overwhelming majority of Swedes voted against any further extension of nuclear power in a special advisory referendum last Sunday. By a combined vote of 76% to 19% with 5% undecided, the electorate registered its approval to phase out Sweden's present nuclear programme within 25 years. Thirty nine per cent of the voters supported the Centre Party-Communist proposal to dismantle the programme within 10 years, 37% supported the Social Democrat-Liberal proposal to use present and planned capacity for 25 years as an emergency measure only, and 19% supported a Conservative option that would leave the door open for the development of uranium mining and the fast breeder.

● Swiss voters in the village of Hagedorf in the north west canton of Solothurn may have blocked effectively further nuclear development in Switzerland last week by refusing to give permission for test drilling for nuclear waste disposal. The 2,500 villagers rejected proposals by the State-backed company Nagra to drill for waste disposal sites by a 3-1 margin, despite

having voted in favour of the government's energy programme last year.

● French residents in the Brittany towns in cap Sizun claimed a victory last week when the provincial prefect at Quimper freed seven anti-nuclear demonstrators arrested during running battles with the police at protests on 29 February. A crowd of several thousand residents shouted "we have won" at the 1,500 police stationed around the Quimper courthouse. M. Jean-Marie Kerloc'h, mayor of Plogoff, called the decision "comforting". After the court decision and the pre-trial mass demonstration of 40,000 people, it is now widely believed that the central government will be forced to back down from its attempt to impose a complex of four nuclear reactors on the strongly nationalistic Breton people.

● In Finland 5,000 demonstrators, including a large number from the countryside, marched through Helsinki last week to show their solidarity with Swedish anti-nuclear protests and their opposition to the construction of a Soviet

designed 1000MW plant. The demonstration was the largest in Finland since the anti-Vietnam war demonstrations of the late 1970s. Finnish environmentalists are demanding that the contract between the state-owned Imatra Voima company and the Soviet export organisations, Atomenergoexport and all other future nuclear decisions be subjected to full parliamentary debate.

● Dutch police arrested 29 anti-nuclear demonstrators who chained themselves to the gates of the Borssele nuclear plant in Zeeland last week. The protest prevented two changes of shift at the nuclear facility. A total of 150 demonstrators, members of the Dutch anti-nuclear group "Break the Netherlands Atomic Chain" padlocked all seven gates at the plant, preventing entrance for 20 hours until their arrest and dispersal by police.

● In Britain, a second Scottish local authority has refused planning permission for test site waste disposal drilling. The Atomic Energy Authority has asked for another public inquiry to be held to try to obtain permission to drill 32 boreholes near Loch Doon, south west Scotland after its proposal was rejected by the Kyle and Carrick county council. The Conservative-controlled council feared that if granted, the proposal would lead to a detailed application for a demonstration disposal plant.

● According to figures released by the Secretary of State for the Environment in parliament recently, the UK civil and military nuclear programmes produce 100m³ of high level liquid wastes, 500m³ high level solid wastes, 450m³ plutonium contaminated waste and 250m³ miscellaneous waste each year. Some medium and low activity wastes including plutonium-contaminated material and reactor decommissioning wastes are dumped at sea.

The total waste stored at civil nuclear power stations at the end of 1979 was 20,000m³. Of this, the total accumulation of high level liquid waste was 1,000m³ at Windscale from the reprocessing of power reactor fuel and 700m³ at Dounreay from the reprocessing of fuel from experimental reactors. In addition, approximately 9,000m³ of high level solid waste and 3,500m³ of plutonium-contaminated waste are in store. The total accumulation at AEA and British Nuclear Fuel sites of medium level liquid wastes, concentrates, sludges and resins, wastes from decommissioning reactors and other plant and other medium level wastes is about 11,000m³.

The National Radiation Protection Board has spent £70,000 since 1977 to assess the radiological consequences of disposing of radioactive waste in geological formations.

EEC

Melt-down experiment go-ahead

FRANCE has removed its objections to an experiment simulating the melt-down of a nuclear reactor, and so removed the last obstacle to the European Community's £530 million, 1979-83 programme for fusion research and support of the Joint Research Centre at Ispra, North Italy.

Italy, as part of its diplomatic activity over European research (3 January, page 3) had refused to endorse the budget of the EEC's fusion programme until France accepted the meltdown experiment, which is now to take place between 1983 and 1986 in the reactor Epsilon at Ispra.

France was planning its own similar experiment at Cadarache, but, says Mr Tom Doyle, head of Epsilon division, "Cadarache has only half the dimensions of ours" and the scale of the experiment substantially affects the results.

The US exerted pressure for the Epsilon experiment — called 'Super-SARA' — to be undertaken as a next step from similar, smaller tests which have been performed on the Power Burst Facility at Idaho. According to a 1979 Nuclear Regulatory Commission report Super-SARA should provide more information on melt-down than any other planned experiment.

"Epsilon is a heavy water reactor" Mr Doyle

told *Nature*; "the active core is 1.5 metres high, compared to a typical research reactor's 0.8 metres." Moreover there are enough channels to make simultaneous tests on 36 fuel rods (compared to 16 at Idaho).

Super-SARA will consist of 20 experiments to simulate loss of coolant in a light water reactor either rapidly, over 10-20 minutes, or more slowly (the 'small break' case as at Three Mile Island). Fuel rods will be taken to the rupture of cladding, but it is intended to leave the rest of the reactor unaffected. This is "a bit of a difficult problem" says Doyle, but not insurmountable.

The experiments are necessary, he says, because calculations are very difficult: "you have a two-phase problem under transient conditions".

The successful flurry of diplomatic activity between Italy and France over Super-SARA began last December, when the EEC Council of Energy Ministers was faced with a French veto. The French High Commissioner for Atomic Energy in the case was Jean Teillac who, as President of the Council of the European sub-nuclear physics organisation, CERN, was resisting Italian moves to 'clarify' CERN's future.

UK attacks mercury directive

THE latest draft environmental directive issued by the European Commission in Brussels concerns mercury emitted into rivers by the chlor-alkali industry — and it has come in for the now familiar sharp attack from the UK House of Lords sub-committee on the environment.

In a report published last week, the sub-committee charges that the EEC directive should not confine itself to one industry (there are other sources of mercury), should deal separately with solid and soluble mercury, and should not specify limits without indicating whether an absolute maximum or some kind of average is intended. Moreover, some of the limits are unduly stringent, says the report.

However, Britain emits more mercury into its rivers than any other EEC country, when the figures are related to chlorine production: 16.9 g per tonne of chlorine compared, say, to 3g per tonne in France.

But the basic difference between the Lords and Brussels is over the difference between "environmental quality objectives" (EQOs) as usually adopted for water in Britain, and the "emission standards" favoured by other EEC members. Although Britain has convinced the Commission to establish both for each

new pollutant considered (mercury is the second, after aldrin, dieldrin, and endrin, and cadmium will be next) the philosophies of the two are too different for them to sit easily together.

EQOs are easiest to establish where the control of river catchment areas is unified, as it is through the water authorities in the UK, and water use, defining necessary quality, a national matter. But in continental Europe rivers such as the Rhine are far from such unification.

"The apprehensions of member states subject to cross-frontier pollution" says the report "rest partly on the fact that an upstream member choosing the EQO alternative route could adopt a water use requiring less stringent standards than a neighbouring downstream member state obliged to use the water for purposes . . . which would demand higher standards".

Britain and the rest of the community are thus likely to have continuing difficulties over environmental standards; and these are accentuated by the greater scientific rigour required when setting EQOs as opposed to emission standards. "It is clear" says the House of Lords report "that the Commission has too few staff available to work on environmental proposals . . . For example, there is no expert on toxicology." The House of Lords will debate the report on 17 April 1980.

Robert Walgate

'Water pollution: mercury' House of Lords Session 1979-80 38th report of the Select Committee on the European Communities. HMSO.

NEWS IN BRIEF

US-Yugoslav interferon agreement

THE National Patent Development Corporation, a private company which is planning to build a pilot plant in New Brunswick, New Jersey, to produce interferon, last week announced that it had signed an agreement with the Yugoslav Academy of Science's Institute of Immunology for regular supplies of the protein.

Under the agreement, National Patent will receive 4.5 billion international reference units of the human leukocyte within the next six months. And within that period, an accord will be reached under which National Patent will be supplied with 10 billion units a month.

Meanwhile the *Boston Globe* reported last week that research workers at the Massachusetts Institute of Technology expect to announce shortly that they have developed a method for producing interferon at only five per cent of current production costs.

The process is said to be based on research carried out in MIT's Department of Nutrition and Food Science, which has shown that human cells can be grown on small beads of starch, and that such a process can be used in particular for cells producing interferon.

Although the efficacy of the technique has yet to be demonstrated, the process has already been licensed exclusively to Flow Laboratories of Virginia. The company is currently negotiating with the National Cancer Institute to supply 50 billion units of interferon using the MIT process, which is claimed to reduce the cost of a million units from \$50 to \$2.50.

The CIA's toxic agents

BIAGEN — the European-based genetic engineering company largely owned by International Nickel and Schering Plough, which recently announced the successful synthesis of interferon — may have a less illustrious predecessor. According to information made public recently by the Church of Scientology, the Central Intelligence Agency developed a machine called Biogen in the late 1950s to manufacture toxic organisms for use in covert biological warfare.

The scientologists, who have been conducting an active campaign to discredit the activities of the CIA, say that the machine was used for 13 years, and may have produced hundreds of pounds of various biological agents and microorganisms, in particular those capable of causing undulant fever and tularemia.

The scientologists also claim that the machine was kept in operation until 1972, three years after President Nixon had publicly renounced the use of biological weapons in warfare.

Frosch approach to space delinquency

COMMANDERS of the National Aeronautics and Space Administration's space shuttle, now due for its first flight early next year, will have the authority "to use any reasonable and necessary means, including physical force if necessary," to maintain order on board his craft, NASA administrator Dr Robert Frosch agreed last week.

Dr Frosch approved a new rule that would give the commander of the space shuttle powers to arrest any member of the space crew — including space scientists on board — and charge him or her with a crime punishable by a \$5,000 fine, a year in prison or both.

Agency officials argue that such rules were not necessary on earlier space flights involving fewer crew members and more constrained surroundings. But the space shuttle will carry seven individuals, four of whom will be civilian scientists. And according to NASA General Counsel S Neil Hosenball, the new situation demands both a formal chain of command and regulations "concerning possible criminal behaviour in space".

As a precedent, Mr Hosenball quoted the case of a technician who had been killed on an ice island in the Arctic after going berserk and threatening other members of a research team tracing the movement of ice-flows. A manslaughter charge was reversed by the Alaska Court of Appeals, which ruled that it lacked jurisdiction over a crime committed on an island that spent virtually all its time floating in the Arctic Ocean.

Oil drills escape US export control

AFTER several weeks of intense debate, the Carter administration announced last week that it is planning to tighten controls on American exports of high technology products to the Soviet Union. According to a statement issued by the US Commerce Department, the new controls will cover areas such as computers and software, manufacturing technology, and "materials critical to the manufacture of high-

technology defense goods".

The new policy follows an extensive review of the government's attitude towards high technology exports, initiated in response to the Soviet Union's intervention in Afghanistan in December. In the area of computers, for example, administration officials stated that standards will be tightened to conform to those of 1976, when restrictions of computer exports to the USSR began to be released.

One exception to the ban will be on the export of oil drilling equipment to the Soviet Union. The administration had been advised that to cut off such exports, in a field where USSR technology is said to be many years behind that of the US, would only encourage the Soviet Union to seek oil supplies in other countries, and in particular to look towards Iran.

Radiation protection on a budget

IF one man-Sievert of radiation were distributed uniformly over the British population, resultant cancers would be thinly distributed and there would be little public reaction. But if the radiation were concentrated in one town, there would be no more cancers (if response is linear to dose) but there would be an outcry because of their concentration.

Considerations such as these have led the UK National Radiation Protection Board to make estimates of the amounts that it would be cost-effective to spend to protect Britain from unit amounts of radiation dose — if it were uniformly or non-uniformly distributed. One man-Sievert uniformly spread in Britain is worth £100,000 of protection, estimates the report (though it could be a factor of five either way). But concentrated in a town of 10,000 people it would deserve protection of £40 million.

NRPB admits its figures 'have no absolute significance', but are intended to be the basis for consultation.

'The application of cost-benefit analysis to the radiological protection of the public'

HSE gets Coalite report

THREE reports discussing the effect of 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin) on workers at the UK firm of Coalite and Chemical Products were handed over to the Health and Safety Executive (HSE) last week. Two weeks ago *Nature* reported Coalite's reluctance to make this information public (5 March, page 2). The report now in the HSE's possession discusses immunological, biochemical and chromosome studies of workers exposed to dioxin at Coalite between 1968-71. An HSE spokesperson is quoted as saying that the Executive is now "assessing and appraising" the reports.

FEATURES

Distorting the epidemiology of cancer: the need for a more balanced overview

The politics of cancer are becoming increasingly polarised with environmentalists taking one extreme view and industrialists the other. **Richard Peto** argues that a more dispassionate and disinterested approach is required for a realistic assessment both of the risks from environmental carcinogens and of the preventative regulations needed

THERE exist, both in the general environment and in certain occupations, chemical or physical agents which increase the likelihood of human cancer. Our political response to this would, in an ideal world where sufficient knowledge was available, depend on the direct and indirect costs of the various possible measures of control, and on how many cancers each such measure would prevent. In the real world, estimates of the direct financial costs of the control of particular agents can easily differ by one or two orders of magnitude, the indirect costs may be grossly exaggerated, or some major indirect costs may be completely overlooked. Worst of all, we have in general no remotely reliable estimates of the numbers of cancers which particular legislative controls would prevent. Consequently, there is wide scope for pressure groups to have considerable influence on public policy.

Historically, the most powerful pressure groups in US society have been the large financial interests, which have almost always put financial advantage before human health. Over the past few years the major tobacco companies have launched massive sales drives in the Third World, which if successful will kill millions of people. (About one in four regular cigarette smokers is killed prematurely by smoking.) In the US, where cigarettes cause well over 100,000 deaths every year from lung cancer or chronic obstructive lung disease, the tobacco industry refuses to accept in public that cigarettes cause either disease, let alone to collaborate in serious public information, and no epithet can suitably describe the collective efforts of their advertisers.

No other industry kills people on anything like the scale that the tobacco industry does, but where other industries have been found to cause cancer (or dust-induced lung disease) in their workers or in

the consumers of their products, their immediate response has usually been to delay acceptance of the findings, to minimise their relevance to current practice, and in general to delay or obstruct any hygienic measures which will cost money. Even when human danger has been unequivocally demonstrated, industrial consortia may actively lobby for controls so weak that (as with the new UK government regulations limiting inhaled asbestos to 1 fibre/ml from 1981) they leave no reasonable safety margin. Large amounts of money are available to mount press or TV publicity campaigns about the homely apple-pie virtues of asbestos, journals financed by the tobacco industry run populist articles which misrepresent research results to lay readers, and some US television journalists are explicitly told always to censor all reference to the dangers of smoking.

Even the scientific literature is not immune from distortion by financial interests. The decades-long argument that "threshold" dose levels of carcinogens must exist below which the general population is absolutely safe has not been entirely motivated by the scientific plausibility of the hypothesis. With increasing understanding of the derivation of tumours from single cells acted on by mutagenic carcinogens, industry is slowly abandoning "threshold" arguments in favour of arguments^{1,2} (where the biological fallacies^{3,4} are somewhat better concealed by the mathematics) that thousandfold reductions in dose can conveniently be "statistically guaranteed" to produce a million-fold or some other enormous reduction in risk.

Even if the scientists who propound such models are disinterested, industrial endorsement of them is not. Much excellent toxicology may be done by industry, and many industrial scientists and managers may be directly and honestly concerned with the prevention of hazards. But so many examples of financially-motivated bias exist that the motives and work of industrial scientists and

consultants are inevitably distrusted.

Over the past quarter century, the "environmentalist" camp in North American society has pressed for (and achieved) stricter control of particular carcinogens in the work-place, the general environment, and the diet. Usually, their efforts have been directly resisted by the relevant financial interests. Inevitably, in view of the scantiness of reliable quantitative knowledge about the cancer risks to man of nearly all carcinogens, the argument has polarised. In the politics of cancer, each side takes a very extreme position. Industry usually argues for the irrelevance to man of animal or *in vitro* cancer tests, or minimises the quantitative hazards and exaggerates the costs of control. The environmentalists usually exaggerate the likely hazards and are largely indifferent to the costs of control.

'The most powerful pressure groups in the US have been the large financial interests which have almost always put financial advantage before human health'

The vacuum of reliable scientific knowledge is such that each side can find scientists who will maintain in courts, in public hearings or in the scientific literature whatever is politically convenient, and it is important to recognise that scientists on both sides of this debate now have career interests at stake in it.

A particularly good example of the biased writings of politically active environmentalists is Samuel Epstein's *The Politics of Cancer* (Sierra Club Books, 1978, revised in Anchor Press, 1979). Epstein outlines, for university-educated but not necessarily science-educated readers, his view of our present state of knowledge about prevention of death from cancer. He concludes that the cure rates for the major cancers have not been improving much over recent years, but that we do know enough now about the causes of cancer for the testing and regulation of environmental contaminants to prevent the majority of US cancer deaths, and that the main obstacles to our doing so are political rather than scientific. He therefore reviews the scientific and political circumstances surrounding a

Richard Peto is a reader in cancer studies at the University of Oxford. This article developed from a review of Samuel Epstein's book, The Politics of Cancer

dozen or so disputed consumer products or occupational hazards, providing much fascinating political detail, and then describes at length the internal politics of the various agencies which research, regulate and litigate in Washington.

Epstein's book has been written to inflame political passions against environmental carcinogens, and parts of it are well worth reading. However, the political punch is often achieved at the expense of scientific accuracy and balance. Despite this, the book has already gained wide and apparently uncritical acceptance even among scientists. For that reason, it is worth considering some of the misrepresentations of scientific evidence which it contains, and some of the more general defects in the environmentalist perspective on cancer.

First, a few details. Epstein's book is very useful as a source of reference to original papers, but it is not in itself a reliable secondary reference because the material presented is so often distorted. Sometimes this distortion is due to the effects of Epstein's vigorous campaigning style on his scientific judgement and is, perhaps, forgivable; at other times it appears to be deliberate, which cannot so easily be forgiven.

For example, consider the (by now generally agreed) finding that incorporation of about 5% by weight of saccharin into rat diets gives a few rats bladder cancer, but has no generally accepted effects on any other type of cancer. By human standards, 5% represents a vast saccharin intake (and so, of course, the industrial "Calorie Control Council" have tried to shrug off these findings). To refute the common reaction that "anything given in large enough doses will cause cancer in animals", Epstein's chief argument is to report that 0.01% saccharin has also been shown to be carcinogenic. In support of this extraordinary claim, he presents in tabular form the control and 0.01% data for selected cancers from certain multi-group feeding experiments, leaving out the observations from those same experiments which would

have refuted it (see table). This appears to be a deliberate attempt to deceive the reader. It is not a casual slip in a 600-page book, as Epstein devotes twenty pages and two full-page tables to saccharin. His entire table 6.4, entitled "Tumours other than the bladder in rodents fed saccharin", appears to be so subject to artefacts of selection that it provides no evidence that saccharin does cause any rodent tumours other than in the rat bladder.

Saccharin is not an isolated example of bias; indeed, I found that in many places where he discussed data with which I was familiar inaccuracies were present, almost always in the direction of accentuating the need for battle with the devils of industry.

Turning to more important matters, Epstein asserts that any benefits from the "less dangerous" cigarettes which the tobacco industry has developed will be outweighed by people increasing their consumption to get more nicotine, and he is therefore in many places particularly scathing about (or even downright opposed to) research into changed cigarette composition. This is a distorted perspective on one of the more promising immediate means of preventing fatal cancers, a quarter of which in America are currently due to smoking.

Smokers of "less dangerous" cigarettes have already been found in various epidemiological studies to have disease rates which are materially lower than smokers of other cigarettes^{6,7}; at autopsy they have far fewer "pre-malignant" histological changes in their bronchi⁸ and, perhaps due to the changes in cigarette composition 10 or 20 years ago male lung cancer death rates in early middle age are now decreasing in North America, in Britain and in Finland.

After lung, the next commonest fatal cancers in the US are those of the breast and the large intestine, for which the most striking epidemiological finding to date is a 90% correlation between fat consumption in different countries and their breast or colon cancer rates (see figure; similar correlations exist for colon cancer¹⁰). Epstein suggests that dietary fat may

'Scientists on both sides of the environmentalist debate now have career interests at stake'

merely be acting as a vehicle for fat-soluble pesticides and industrial chemicals, which predictably emerge as his villains yet again. However, his suggestion is implausible: countries with high levels of contamination do not stand out from the general cancer/fat relationship, colorectal and breast cancer were common long before the widespread use of pesticides, and in experimental animals high-fat or low-fat diets can greatly enhance or reduce the risk of cancer¹¹. Something more interesting is waiting to be discovered in our diet than simple contamination by carcinogens.

The fat-associated and smoking-derived cancers collectively account for more than half of all cancer deaths, and people concerned with cancer politics should try to understand them considerably more accurately than Epstein appears to. One can list many other instances where Epstein's content or style are misleading or unbalanced. For example:

- The discussion of alcoholism and cancer is entirely erroneous because of failure to standardise properly for age.

- One of Epstein's chapters ends: "Eisenhower warned against the growing national threat of the military-industrial complex. The medical-industrial complex now appears to be as serious a threat".

- There is idealisation of the value of long-term animal tests with concomitant denigration of the value of the Ames test and other short-term tests. This is one of Epstein's most inexplicable errors of scientific judgement, unless he wants cancer tests to be difficult and expensive for industry.

- He is irritatingly puritanical, sneering at "the plastic age which symbolises how the value of our lifestyle has been degraded".

- He seeks by stylistic tricks to attribute to oral contraceptives some of the established hazards of hormone replacement therapy and of diethylstilboestrol.

- He claims that cancer costs the US economy over \$25 billion per year. (In fact, cancer must be prevented for humane, not for economic reasons; without cancer, there would be three or four million more retired North Americans to support, costing over \$25 billion per year).

And so on. He seems so certain about everything — how can anybody be justified in being so certain about so many details? Sometimes I know he's wrong, but more often (especially in the many places where inconclusive scientific results are presented as established fact) I know that nobody knows for sure. Lewis Thomas once wrote, in another context: "The sceptics in medicine have a hard time of it. It is much more difficult to be convincing about ignorance concerning disease mechanisms

Table: Data from OTA report⁵ on the tumour sites selected for presentation in Epstein's book to substantiate the claim that 0.01% saccharin is carcinogenic. Groups selectively omitted in Epstein's book are marked with an asterisk. These omissions substantially alter the implications of the original data.

Saccharin dose (% in rat diet; these doses have no material effect on longevity)	Male or female lymphosarcomas (FDA, 1948)	Female breast (FDA, 1973)	Male breast (FDA, 1973)
0 (control)	0/20* (0%)	6/26 (23%)	6/29 (21%)
0.01	8/14 (57%)	14/30 (47%)	14/25 (56%)
0.1	5/16 (31%)*	13/34 (38%)*	9/27 (33%)*
0.5	2/15 (13%)*	—	—
1	1/18 (6%)*	12/30 (40%)*	8/27 (30%)*
5	10/17 (59%)	12/27 (44%)*	7/25 (28%)*

*Omitted in Epstein's book.

⁵In addition to these 20, since some other sweeteners were being tested concurrently, 34 other control animals were studied in the same experiment, and the 1977 OTA review of these data, considering all the control animals to be equivalent, cited 9/54 control lymphosarcomas. (0/10 saccharin controls of each sex were studied, not 0/20 as Epstein inadvertently indicated.)

than it is to make claims for full comprehension, especially when the comprehension leads, logically or not, to some sort of action. When it comes to serious illness, the public tends, understandably, to be more sceptical about the sceptics, more willing to believe the true believers."

Epstein (like many others) is unjustifiably definite about three major issues. He seems certain that even after the effects of cigarettes have been allowed for, Americans live in an era of rapidly increasing cancer rates. But trends in recorded cancer death rates (and, perhaps more so, recorded incidence rates) over the past quarter century are biased upwards (since the cure rates for the major cancers have not materially improved) by improvements in medical care and cancer counting. These improvements have

'The NCI-NIEHS report shows how a group of reasonable men can collectively generate an unreasonable report'

affected all sectors of US society, but most particularly old people and previously poor people, especially blacks. Epstein, along with most other US commentators, does not allow for these biases even to the limited extent of restricting his attention to trends in age-specific mortality rates among middle-aged whites, where they might be expected to be least prominent.

Among middle-aged whites during the past quarter century, cancer cure rates have not materially improved, but some US cancer mortality trends seem to be genuinely down (stomach, cervix) while some seem to be genuinely up (pancreas, melanoma, and certain lymphomas). I can discern no net pattern other than that due to the massive effects of smoking on lung cancer, although no extension to 1978 yet exists of the excellent 1950-67 trend analyses in NCI monograph 33. In Britain, the same is true¹² as long as we examine mortality in middle age. (Interestingly, although Epstein emphasises that bladder cancer death rates among whites in the industrial north-eastern US are high, this may not be chiefly due to any current industrial hazard, for they have been decreasing both relatively and absolutely for a quarter of a century¹³.)

Epstein also seems certain that the majority of human cancer is caused by chemical and physical agents in the environment and could be prevented by their testing and regulation. There is no sound scientific basis for this certainty. Since the cancers (lung, breast, large intestine) which are commonest in the US are rare in certain other countries, and *vice versa*, they probably really are preventable, but (see figure) not necessarily by regulation of any environmental pollutants

or food additives. Indeed, one of the most intriguing animal findings is the effect in many studies of gross aspects of diet on cancer; for example, mice randomised between 5g of food once daily and *ad lib* consumption averaging 6g/day of the same food, had respectively 8% and 64% spontaneous mammary tumours¹⁴, and the role of dietary fat¹¹ has already been discussed.

Thirdly, Epstein seems certain that at least a quarter of all cancer deaths are attributable to occupational exposure to carcinogens. There is as yet no good evidence for hazards of anything like this magnitude, and there is clear evidence that many of his particular claims are exaggerated. For example, he says that asbestos has led to approximately 50,000 deaths per year in the US from cancer and related disease (referencing a paper by Selikoff¹⁵ which actually neither makes nor implies any such claim). This is sheer nonsense; of 50,000 asbestos deaths, several thousand should be certified as being due to pleural mesothelioma, yet only several hundred per year are thus certified.

Likewise, Epstein cites with approval (indeed, he describes it as being of "epochal significance") Health, Education and Welfare Secretary Califano's absurd 1978 estimate, in a speech to labour union leaders, that as many as half of the 8-11 million workers who have been exposed to asbestos could develop serious diseases such as cancer or asbestosis. In his second edition, Epstein draws extensively on Califano's source, a curious but extremely influential document which has been circulating privately for the past year or more. This unpublished typescript, with no listed authors, was prepared by a working group of nine well-known scientists including Arthur Upton and David Rall, the National Cancer Institute and National Institute of Environmental Health Sciences directors,

'Present day cancer rates and trends are probably not dominated by occupational carcinogens or environmental pollutants'

both of whom still seem more ready to defend than to repudiate it.

Entitled "Estimates of the fraction of cancer in the US related to occupational factors", it shows how a group of reasonable men can collectively generate an unreasonable report. The group multiplied the 12 million workers exposed in any way in 1972-4 to any of asbestos, As, Ni, Cr, benzene or petrochemicals by the very large risk factors (e.g. fivefold lung cancer excesses) typical of much more extensively exposed industrial populations, finally multiplying again by "4-5" to allow for the additional cancers that will be caused by these six agents among workers exposed to them at times other than 1972-4. (In casual disregard of dosimetry, this whole process is very like predicting 100,000 occupational lung cancer deaths per year among non-smokers due to their exposure to other people's cigarette smoke at work, "since 20% of heavy smokers get lung cancer").

These assumptions "predict" over 200,000 extra respiratory tract cancers per year in the near future due to the above six agents alone (and are the sole source of the currently widespread prediction of "20-38%" of cancers being due to occupation). But, in reality, fewer than 90,000 males/year get respiratory tract cancer in the US (and most of these are due to cigarettes and not to occupation at all), and moreover the US male rates in the first 25 years of working life are currently decreasing! A prediction of 100-200,000 extras due to the above six agents is clearly

Figure: data⁹ plotting for 39 countries age-versus total dietary fat (animal or standardised breast cancer death rate vegetable).

very unrealistic.

The unreality of the whole method is further highlighted by the fact that the assumptions "predict" $7,300 \times 4.5$ nickel-oxide induced occupational lung cancers/year. Since nickel refining causes a lot of nasal as well as lung cancer, we would presumably then also soon "expect" something like 13,000 nasal cancer death certificates per year among nickel workers. Nickel has already been widely used for decades, so many thousands of these should presumably already be evident. In reality, each year in the US population there are only 300-odd male and 200-odd female nasal cancer death certificates. The majority of these are not ex-nickel workers and no marked trends are evident. This demonstrates the unsoundness of the NCI-NIEHS methodology.

Unfortunately, such exaggerated estimates are so much what many people want to believe of modern society that they have now achieved a life of their own, and although they are utterly without foundation they are quoted widely, repeatedly and reputably both in the lay and scientific press. In Geneva the International Labour Organisation reportedly endorsed them, as did the Toxic Substances Strategy Committee in their recent draft report to the US president¹⁶, and they have been used in OSHA to emphasise the need for stricter laws. Most recently, the UK trade union the Association of Scientific, Technical and Managerial Staffs (ASTMS) released a policy document which appears to have been strongly influenced by Epstein's book, and which is notable for its prominent but erroneous assertion, derived solely from the foregoing unpublished US typescript, that 20-40% of current UK cancer deaths are caused by occupational carcinogens.

Epstein now claims that these exaggerated estimates seriously underestimate the impact of industrial carcinogens. There is obviously a valid political need to exaggerate the importance of the preventive measures we can already

death rates¹² should be more widely known.

My criticisms of Epstein's science, however, must be viewed in the light of the continued resistance of many industries to reasonable controls. One has only to read some of his descriptions of industrial behaviour to see where his passion comes from, and a suitably sceptical reader could derive much important information from the dozen or so detailed case-histories of particular carcinogens that make up the bulk of this book. But, although I cannot prove it, I suspect that environmentalists as a whole (including Epstein and those US and British trade unions which have already modelled their public statements closely on his book) would be better

'The politics of cancer is dominated on both sides by exaggeration'

respected and could therefore press more effectively for controls in particular instances if their overview of cancer was more balanced in the following ways:

- if they accepted that present-day cancer rates and trends are probably not dominated by occupational carcinogens or environmental pollutants (especially since they could still warn that future rates might perhaps be so dominated unless present-day exposures are regulated²⁰);
- if their chief concern was with the identification and control of the few major determinants of human cancer (or, in an industrial context, the few major industrial carcinogens) rather than the large multitude of sins which Epstein denounces;
- if they discussed the costs and benefits of research into the control of toxic substances in the context of other possible ways of improving longevity (bad diet and tobacco in rich countries, malnutrition and infective and parasitic diseases elsewhere);
- if they took the costs of imposing restrictions on society more seriously. Epstein's general assertion is that the total direct and indirect costs of failing to regulate usually exceed the real costs of the testing and regulation, but I suspect that this is a slogan to avoid political embarrassment rather than a carefully researched conclusion;
- if they accepted that for most toxic chemicals we have both qualitative and vast quantitative uncertainty about the health benefits of restriction.

Particularly, even if the sort of grossly biased interpretation which Epstein applied to the animal saccharin data is avoided, the results of animal experiments simply are not an uncomplicated key to human hazard identification. First, moderate alteration of gross aspects of the diet of animals greatly modifies their spontaneous tumour onset rates¹¹ (so, for example, increasing the sugar content of rat diets may increase their cancer rates

more than the equivalent amount of dietary saccharin would have done¹¹). Also, any chemical which causes proliferation or necrosis in any organ that is subject to spontaneous cancers is likely to modify the onset rate of tumours in that organ, and since the aim of most animal experiments is to study a dose which is nearly, but not quite, sufficient to cause significant weight loss or mortality within three months, it is not surprising that so many chemicals at such doses can cause cancer in animals.

However, it may be that where adversary politics operate one needs views at both extremes in order to get a balanced outcome. And there is a possibility that over-emphasis on the avoidance of scientific error would emasculate the environmentalist passions and merely lead to my own rather inactive conservatism. (After all, no scruples about scientific certainty of safety usually precede the widespread introduction of new chemicals, so should the imposition of prudent restrictions require absolute proof?)

Environmentalists with biased judgments and a quasireligious certainty of right will fight more battles than any reasonable sceptic would do, and even if their victories confer 10 or 100 times less benefit on humanity than they imagine, they will in the long run probably do more good than harm — unless they materially reduce food production, distort research priorities, or direct attention away from the smoking problem in the process. Epstein justly quotes, from the 1st century AD, the Plutarch chronicles: "He who in time of faction takes neither side shall be disenfranchised". So, I feel, should both environmentalists and industrialists who suppress or deliberately misinterpret data, but they probably won't be. For the moment, the 'politics of cancer' is dominated on both sides by exaggeration. □

'For most toxic chemicals we now have both qualitative and quantitative uncertainty about the health benefits of restriction'

implement, but in the long run we do also still need to discover the main preventable causes of cancer other than smoking. Bearing both these needs in mind, there are limits beyond which it is not even politically wise to distort the science of cancer, and some of today's exaggerations may well transgress those limits. CORRESPONDENCE

Liberties with energy

SIR,—Gerald Leach (*Nature*, 21 February, page 714), suggests that the pursuit of a high conservation/low energy strategy would not touch personal liberties. No doubt this can be so, but if this policy is maintained it is difficult to believe that a really major effect on fuel conservation is likely to be achieved. There have been many cases in industry in which fuel conservation has actually been of financial advantage to the firms concerned, but it seems likely that the proportion of firms for which this is true will decrease as time goes on, and that many firms will find the value marginal if not negative.

In a depressed and highly competitive period it is very unlikely that firms will at all readily undertake extra expenditure which is not immediately productive, and firms exerting freedom of choice are likely to stay as they are. The likelihood therefore that we shall do too little too late on a voluntary basis is really quite large, in which case Gerald Leach himself says that energy conservation may have to be forced through by controls on individuals.

I am not myself too much bothered by this. The interference with civil liberties would be little more than the controls exerted by fire, smoke control and town-planning regulations. At the same time, I can see no reason to suppose that any protection of nuclear installations that may be necessary should have a worse effect on civil liberties than the similarly necessary protection of many industrial activities such as chlorine production or the manufacture of nylon precursors at Flixborough. Freedom to walk into other people's factories does not come high on my list of vital freedoms, whether they are processing nuclear wastes or military weapons or indeed cigarettes. A severe shortage of power with strict rationing would seem to me a more serious limitation of my liberties than would the fact that I could not get into a nuclear processing works without passing somebody carrying a revolver.

If there is a genuine risk of a terrorist attempt to kill many thousands of people in a single major incident, we should have to introduce a great many controls much more onerous than the guarding of a few well defined nuclear establishments in limited areas. One would, for example, need to control an appreciable area of South Essex and North Kent to ensure that a few saboteurs with a rocket launcher should not blow up the Canvey Island stores of liquified natural gas some dark night with a westerly breeze.

Yours faithfully,

J. H. FREMLIN

CEGB on radiation

SIR,—Further to the item headed 'UK Radiation Study Overestimates Safety' (14 February, page 614). I wish to point out that the radiation dose data supplied by the Central Electricity Generating Board to the Health and Safety Executive and also published elsewhere does include the doses received by workers other than those directly employed by the CEGB. We consider it important to include the radiation doses of all classified workers in the dose data relevant to the operation of CEGB nuclear power stations. Only by using such data can sensible comparisons be made between the doses received at nuclear power stations in the UK and those in other countries.

You may be interested to know that the total dose received by non-CEGB classified persons at all CEGB nuclear power stations in

1978 was 236 man-rem, and that received by CEGB personnel was 1399 man-rem. The mean dose per man for each category was 168 mrem and 257 mrem respectively.

Yours faithfully,

R. B. PEPPER

Health and Safety Department, CEGB,
London, UK

Lost in translation?

SIR,—Your readers may know that Nobel Prize lectures are translated into many languages. Mine, delivered in 1977, described the growth of our understanding of non-crystalline semiconductors and contains the following sentence. "The discovery of this property of glasses" (namely that they cannot be doped) "certainly makes Kolomiets" (Leningrad) "one of the fathers of the branch of science that I am describing, as were others in Eastern European countries, notably Grigorovici in Bucarest and Tauc in Prague." Grigorovici remains in Bucarest, I believe retired; Tauc is in America.

For reasons unknown to me, the translated version published by the Czechoslovak Journal of Physics, with the permission of the Nobel Foundation, omits the last two of these names. A letter to the editor-in-chief from the Nobel Foundation, dated 7 November 1979 and asking for an explanation has not yet been answered.

Yours faithfully,

NEVILL MOTT

Department of Physics, University of
Cambridge, UK

Insignificant figures

SIR,—Uncritical recording of estimations with numbers that include insignificant figures is a plague in scientific literature. Although technological advancements make possible increasingly more accurate measurements, overall precision is limited by the less accurate step involved. Moreover, modern calculators tend to increase the number of figures without any relation to significance.

To quantify this abuse we have examined a selection of first class journals looking for clearly insignificant figures. The results exceeded our expectations: in the issue(s) corresponding to one month of 1979 all journals examined had several papers with insignificant figures. The journals are: *Eur. J. Biochem.*, *J. Biol. Chem.*, *Nature*, *Proc. Natl. Acad. Sci. USA*, and *Science*. For illustration, five examples taken from the above sampling are listed below (followed by appropriately rounded numbers in brackets):

enzyme activity: 913,856 U (914×10^3)
enzyme activation: $1005 \pm 80\%$ of control (10
fold activation ± 1)

glycogen in muscle: $22.43 \pm 2.89 \mu\text{mol/g}$
($22.4 \pm 2.9 \mu\text{mol/g}$)

one type of cell in mice spleen:

$104,662 \pm 18,937$ ($105 \times 10^3 \pm 19 \times 10^3$)

weight of fed female ticks: 297.26 ± 63.6 mg
(297 ± 64 mg)

From extrapolation of this small sample it seems that over 10% of currently published scientific papers contain insignificant figures.

To obtain useful information from these multifigured numbers the reader has to do some mental operations (even if largely unconsciously), to eliminate from consideration the irrelevant figures, keeping three at the most. Would it not be much better to weed out the inordinately large numbers once and for all from (computer) calculation to publication? Insignificance usually runs parallel to irrelevance. Results should be both analytically significant and scientifically relevant; everything else would be noise. For instance, the liver of a young rat may weigh in

a balance as 6.2345 g; but because of the uncertainties on how much is really "the liver" (vascular pedicle, blood, and other factors), only 6.23 g would be relevant in most cases. Four or more figures would generally be mere pseudoprecision, even if analytically significant.

The rampant pseudoprecision of most results given with 4 to 6 figures must be stopped. It is suggested that authors should carefully consider the significance of the results so that only the last given figure is tentative. This practice will usually limit, in the presentation of results, the number of figures to 3, and in many cases to 2 or even 1. Obviously this norm does not apply in the case of serial numbers, dates, etc. For arithmetic means, with non-negative data, if the coefficient of variation ($\sigma/m \times 100$) is greater than 5, the mean should be expressed with the same number of significant figures as the individual data, since such a dispersion does not justify, in general, a greater precision. Only if it is smaller than 5, an additional significant figure could be appropriate. Exponential forms (i.e. 914×10^3) will aid and simplify in most cases the final presentation of results with a number of figures limited to the significant ones.

Finally we propose to the editors of scientific journals to include in the instructions to authors a statement that manuscripts with obviously insignificant figures would not be accepted, perhaps adding that manuscripts with results with more than 3 figures should have an explicit (and acceptable) justification in the text or in the accompanying letter to the editor. Scientific objectivity would benefit, and the work of the scientists would be easier. Implicitly, this policy would recognise the fact that some scientists spend months or even years improving conditions to add one significant figure to a constant. Moreover, scientific publishing would be a little less expensive, nowadays a not insignificant consideration.

Yours faithfully,

ALBERTO SOLS

JOSÉ LUIS CARRASCO

Autonomous University of Madrid, Spain

Exhibitionism

SIR,—Your correspondent Jim Ritter, in an otherwise perceptive feature (3 January, page 6) on the proposed French science museum at La Villette, displays his ignorance of what contemporary museums have been doing during the last two decades. Far from being sources of magical effects — 'black boxes with pushbuttons' — they have developed a vast array of exhibits and programmes that make science more understandable and accessible to public visitors. Modern science museums demystify science and technology and suggest that, although complex, science can be understood, controlled, and even enjoyed.

The Association of Science-Technology Centers, to which more than 100 museums belong, would be glad to provide an itinerary of museum travels on several continents to bring him up to date.

I would recommend a tour through the tactile gallery and the visual perception exhibits of the Exploratorium (San Francisco), the human reproduction and sexuality exhibit at the Ontario Science Centre (Toronto), the plumbing exhibit and the *Food for Life* exhibit at the Museum of Science and Industry (Chicago), or the exhibition *It's About time* at the Franklin Institute (Philadelphia).

Your faithfully,

MICHAEL TEMPLETON

Association of Science-Technology
Centers, Washington DC, US

A closer look at Saturn's magnetosphere

from S. W. H. Cowley

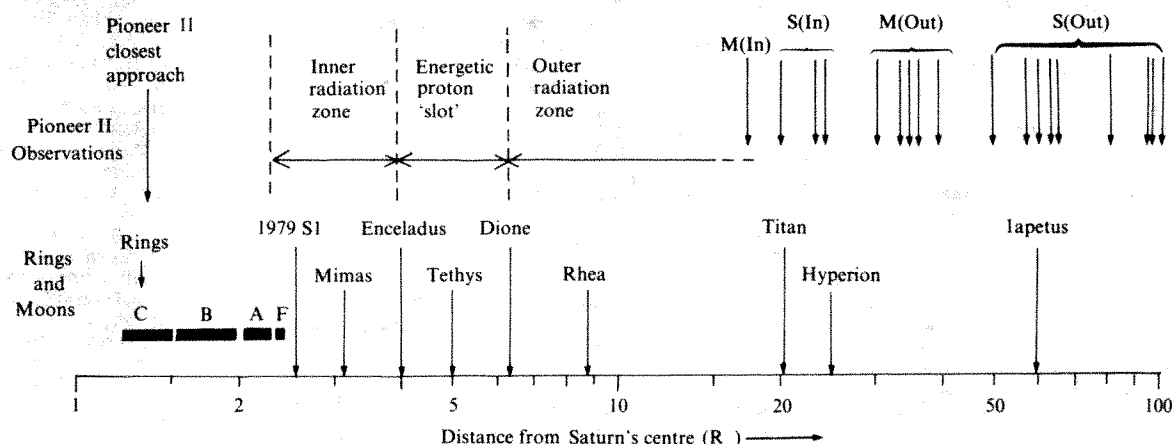

At the beginning of September, 1979 US spacecraft Pioneer 11 undertook the first close survey of the planet Saturn, approaching within 21,000 km of the visible cloud-tops. Pioneer 11 was launched in April, 1973 and had previously made the second Jupiter fly-by in December, 1974, one year after Pioneer 10. All eleven of the spacecraft's instruments which had been operating at Jupiter were still functioning 5 years later at Saturn, and sent back data on the planetary magnetic field and charged particle environment, as well as observations of the planet and its rings and moons in the ultraviolet, visible and infrared bands. A recent issue of *Science* (207; 1980) was devoted to the Pioneer results and here I shall concentrate on the discoveries made by the particle and magnetic field detectors on Pioneer (see Wolfe *et al.*, Smith *et al.*, Simpson *et al.*, Van Allen *et al.*, Trainor *et al.*, Filius *et al.*, Gehrels *et al.* and Acuna & Ness in that issue of *Science*). These included the fourth magnetosphere in the Solar System (after

Earth, Jupiter and Mercury), a new Saturnian ring and at least one new moon.

Saturn had been suspected for some time to possess a strong dipolar magnetic field, such that the planet would be surrounded by a large cavity in the solar wind plasma (which pervades the Solar System) containing the planetary field — a magnetosphere. In 1975 radio bursts from the planet, characteristic of magnetospheric plasma processes, had been detected and an equatorial field strength of ~ 1 gauss inferred (compared with ~ 0.3 gauss at Earth and ~ 4.1 gauss at Jupiter), a value which agreed well with deductions from an empirical 'magnetic Bode's law' which relates the magnetic dipole moment to the planet's spin angular momentum. Using ~ 1 gauss for the surface field strength it was estimated that the magnetosphere would extend to $\sim 40 R_S$ (R_S = Saturn's radius = 60,000 km) on the dayside, the boundary (magnetopause) location being determined by the point where the solar wind dynamic pressure and

the planetary magnetic pressure just balance. The magnetosphere would then always incorporate both the rings of Saturn and all the moons out to Hyperion, as indicated in the accompanying figure.

Pioneer 11 approached Saturn very nearly along the noon meridian (along the Saturn-Sun line), but did not in fact enter the magnetosphere until it was $\sim 17 R_S$ from the planet, as indicated by M(In) in the figure, less than half the expected distance. Subsequent magnetic measurements soon revealed the primary cause to be a rather weaker planetary field than anticipated. The equatorial surface field is ~ 0.2 gauss, with the same polarity as Jupiter's field, but opposite to that of the Earth and Mercury. In swinging round Saturn, nearly in the equatorial plane, Pioneer 11's trajectory was deflected through nearly 90° , and the spacecraft moved out from the planet nearly along the dawn meridian. In this direction the magnetopause is expected to be at a rather larger distance than at noon, and due to

Logarithmic scale plot of the position of Saturn's rings and moons, and their relationship to Pioneer 11 observations. The new F ring and moon (1979 S1) have been included, but further small moons may exist between the orbits of Mimas and the outer edge of the A ring. The D ring inside the C ring, reported from Earth observations, apparently does not exist, and no definite detection of a tenuous E ring extending out to 5 or 6 R_S was made. The moon Phoebe at $216 R_S$ has been omitted. Symbol M refers to the magnetopause (the outer boundary of the magnetosphere) observed during the noon inbound (In) and dawn outbound (Out) passes of Pioneer 11, while S indicates detection of an upstream bow shock in the solar wind.

boundary fluctuations five crossings were observed between 30 and 40 R_S . In all, Pioneer 11 spent some 2½ days within Saturn's magnetosphere.

A most surprising aspect of the magnetic data is that Saturn's field shows no detectable periodicity at the planetary spin period (~10 h), implying that the dipole moment vector is aligned within ~1° of the spin axis. This observation sets an important new constraint on dynamo theories of the origin of planetary fields, as it had generally been supposed on the basis of the other planets that a tilt angle of ~10° might be fundamental. It also frustrates attempts to measure accurately the internal rotation period of the planet.

Properties of the magnetosphere

In general, the structure and properties of magnetospheric plasmas depend very strongly on the nature of the plasma flow within the magnetosphere. Simple estimates before the Pioneer encounter showed that the overwhelmingly dominant flow in the case of Saturn (and Jupiter) should be simple corotation with the planet. This is unlike the Earth's magnetosphere, where a solar-wind driven convection rather like that in a falling raindrop is usually dominant, and where only a rather small 'core' of dipolar field lines near the Earth corotate with the planet. The difference arises mainly from the much higher dipole moments of Jupiter and Saturn compared with Earth, combined with their faster rotation rates.

In a corotating magnetosphere the only direct source of plasma is cold ions and electrons from the planet's ionosphere, together possibly with a lunar contribution if any emitting moons happen to lie within it (for example the volcanic moon Io in Jupiter's magnetosphere). This thermal plasma will be the dominant component in terms of number density inside such magnetospheres. However, more energetic charged particles originating mainly in the solar wind can become trapped in the outer part of the magnetic field if the flow fluctuates, as is always the case in practice, and the fluctuations will then diffuse these particles deep into the corotating region. An equilibrium energetic particle radiation belt will then be formed inside the magnetosphere (like the Van Allen belt inside the Earth's corotating 'core'), in which diffusion steadily feeds particles inwards from the outer source into the internal sinks (for example, absorption by the planetary atmosphere, or by moons and ring material).

The Pioneer spacecraft were not adequately instrumented to measure the dominant thermal plasma component with particle energies in the eV to keV range, but some information can be extracted from

the solar wind instrument under favourable circumstances. At Saturn, corotating thermal plasma was nearly continuously observed by Pioneer 11 during the inbound pass and distinct flux peaks were observed at the distances corresponding to the orbits of Dione and Tethys. The ionic component of this plasma appears to be mainly O^+ (or possibly OH^+) such that the source may be sputtered or photodissociated ices originating at these bodies.

Much more information is available on the energetic radiation belt particles, measurements by four instrument packages being made in the energy range from several tens of keV up to several tens of MeV. The flux of protons at fixed energy initially increases steeply with decreasing distance from the planet (as expected from inward diffusion, since particles gain energy proportional to the field strength as they move inwards). However, a peak is reached at ~7 R_S and then fluxes fall precipitately by more than a factor of 100, reaching a minimum value at the orbit of Enceladus at ~4 R_S . Absorption by Dione, Tethys and Enceladus (see figure) may be significant in forming this proton 'slot', but particle precipitation into Saturn's atmosphere due to scattering by waves excited in the thermal plasma may have a major role.

Inside the orbit of Enceladus energetic proton fluxes again rapidly rise with decreasing distance, reach a secondary peak at ~2.7 R_S before finally falling by more than three orders of magnitude to below detectability at the outer edge of the A ring. Within this inner zone of proton fluxes deep and narrow absorption features occur at the orbit of Mimas at 3.09 R_S and also at 2.52 R_S , corresponding to a previously unknown moon, designated 1979 S1, which had been detected a few hours previously on Pioneer 11 images. In addition, absorption features associated with the F ring (also newly seen on these images) were observed between 2.34 and 2.37 R_S , together with a flux plateau at 2.81 R_S which may correspond to absorption by a rather smaller new moon. The proton flux increases seen on the inside of these absorption bands seem too sharp to be consistent with the simple inward diffusion picture, and it is likely that a second source of energetic protons contributes to the formation of the inner zone, possibly the debris of cosmic ray interactions with Saturn's atmosphere and ring material. The energetic electrons show many features which are similar to the protons, but only the lower energy particles are lost in the 'slot' region. Fluxes above ~1 MeV continue to increase across the slot, if at a reduced rate, before falling to very low levels at and within the inner edge of the A ring. In general, the particle fluxes measured while the spacecraft passed under the rings were by far the lowest observed since the instruments had left the laboratory.

Pioneer's near miss

A final extraordinary event took place during the ~4 minutes in which Pioneer 11 crossed the 1979 S1 moon absorption band inbound to Saturn. For ~10 s a deep depression in the fluxes was observed by all instruments capable of such resolution which were then above background, implying that Pioneer 11 had actually passed through the flux tube containing the moon, avoiding collision by only a few thousand kilometres. The width of the flux 'hole' indicates a lunar radius of ~100 km. Similar sharp features were seen in the F-ring absorption zone, due either to more moons, or to non-uniform distribution of ring material. A final possible lunar-related disturbance was seen on the outbound pass at ~20 R_S when Pioneer 11 was ~6 R_S downstream from Titan (Saturn's largest moon) in the corotating flow. Large amplitude oscillations were observed in the magnetic field for about 2 h, possibly indicating a hydromagnetic wake produced by Titan. The corotation speed at these distances is ~200 km s⁻¹.

In conclusion, the Pioneer 11 mission to Saturn has provided a wealth of new information about the particle and field environment of the planet but leaves many questions only partly resolved, particularly as regards the thermal plasma and its sources, the nature of Titan's interaction with the magnetosphere and the existence of small moons inside the orbit of Mimas. We will not have to wait too long for some of the answers. Voyager 1 will make the second Saturn fly-by in November 1980, while Voyager 2 will reach the planet in August 1981, *en route* to Uranus. Meanwhile Pioneer 11 will continue on its way to become the second spacecraft to escape the Solar System, roughly in a direction opposite to that of Pioneer 10. It will be tracked and data on the interplanetary medium acquired into the middle 1980s. □

100 years ago

The work of casting the lenses of the great refracting telescope of the Paris Observatory has already begun at Feil's establishment. The founding of the flint disc has taken five days, and the annealing a full month. A like operation will soon take place for the Bishofsheim Observatory instrument.

A correspondent of *La Nature* sends that paper a photograph of a curious phenomenon met with in the cold of December last. It shows a bottle which contained a solution of nitrate of silver (1 per cent). The cork is forced out and imprisoned at the extremity of a long cylinder of ice, due to increase of the volume of the mass in freezing.

From *Nature* 21, 25 March, 500; 1880.

Monoclonal antibodies and immunity to malaria

from F.E.G. Cox

UNTIL the middle of the 1960s there had been very little success in immunising laboratory animals against malaria parasites and many workers felt that this meant that the possibility of a vaccine against human malaria was remote or even non-existent. The past decade, however, has produced abundant evidence that immunisation against these parasites in laboratory animals is not only possible but is in fact remarkably easy. This is unfortunately not really due to any major scientific breakthrough but to the judicious use of suitable combinations of strains of parasites and hosts in which the balance of the immune response is tipped in favour of the host. It is probably as difficult today to immunise random-bred strains of laboratory mice against *Plasmodium berghei* as it was 10 years ago, but avirulent parasites, such as *P. yoelii* and *P. chabaudi*, in certain strains of inbred mice are relatively easy to protect against even when the parasites have been secondarily selected for virulence.

Those working with primate malarias are even less fortunate for they have no avirulent parasites to choose from and are also limited to a small range of random-bred hosts. For the reasons outlined above it is possible to argue that many rodent malaria models are unrealistic but, nevertheless, the fact that protective immunity against any kind of malaria can be induced artificially does open the possibility that the mechanism involved might be relevant to the human disease.

In this context it is important to distinguish between the experimental host and the parasite itself. Undoubtedly man, monkeys and strains of mice differ widely in their ability to handle a complex antigen such as a malaria parasite. On the other hand, all malaria parasites are intrinsically similar in that in the life-cycle the sporozoites, injected into the blood by a mosquito, undergo a single multiplicative phase in the liver resulting in the release of merozoites that enter red blood cells to undergo a second phase of multiplication (or schizogony) resulting in further merozoites that invade fresh red cells to repeat the cycle until the host dies or mounts an effective immune response. The sexual stages of the life-cycle are largely irrelevant or peripheral to protective immunity although immunisation against gametocytes inhibits development in the mosquito (Mendis & Targett *Nature* 277, 389; 1979). In practice, many workers short-circuit the life-cycle by passaging infected blood thus eliminating the sporozoite and liver stages. Biochemical and ultrastructural studies suggest that

there are no fundamental differences between the malaria parasites of man and laboratory animals and, in view of the similarities in the life-cycles, it seems reasonable to assume that, as far as the parasite is concerned, what happens to it in an immunised mouse or monkey is likely to be similar to what happens to it in man.

The three major (and only possible) candidates for a specific vaccine are the sporozoite, the blood schizont and the merozoite. These three forms possess stage-specific antigens so the possibility of one of these inducing any immunity against the others is remote. The schizont has been widely used in experimental work but, notwithstanding the light that such studies have shed on our understanding of immunity to malaria, its practical potential is limited. This is mainly because there is considerable evidence to suggest that malaria parasites undergo some kind of antigenic variation and that any immunity produced is not only stage but also variant specific (Brown *Ciba Foundation Symposium* No. 25, 35; 1974).

This leaves the sporozoite and the merozoite, neither of which seems to be affected by the problems of antigenic variation (Cohen *Proc. R. Soc. Lond. B.* 203, 323; 1979). Sporozoites are logical targets because they are present before any clinically apparent infection. The use of irradiated sporozoites as antigens has been pioneered by Professor Ruth Nussenzweig at the New York University Medical Center and promising results have been obtained in mice, monkeys and man. The arguments against the use of sporozoites are that they probably need to develop in the liver to induce immunity and, as the protection is stage-specific, a single parasite entering and maturing in the liver after challenge will initiate an infection. Furthermore, sporozoites are at present difficult to obtain and multiple immunising doses have to be given. The alternative approach, a merozoite vaccine, has been developed by Professor Sydney Cohen and his colleagues at Guy's Hospital, London. This has also been successful in primates but the arguments against this approach are that there is no protection against the stages in the liver and that the vaccine is not effective unless administered in fairly large quantities with an adjuvant. The supply of merozoites for the preparation of antigen has been facilitated by the development of effective *in vitro* cultivation techniques (Trager & Jensen *Nature* 273, 621; 1978).

Even using the most favourable combinations of host and parasite, it is clear that all that can be done in terms of immunising animals with sporozoites or merozoites has been done and that the next stage will be to identify, isolate and purify the actual antigens involved in protection.

Biochemical techniques for the isolation of such antigens are time consuming but there is already evidence that potentially important antigens occur on the surfaces of sporozoites (Nardin & Nussenzweig *Nature* 274, 55; 1978; Aikawa *et al. J. Protozool.* 26, 273; 1979) and merozoites (Deans, Dennis & Cohen *Parasitology* 77, 333; 1978).

An obvious approach to the identification and characterisation of antigens likely to be of importance in protection is to use monoclonal antibodies produced by hybrid cells one of which has been derived from a lymphocyte actually producing antibody in an infected or immunised animal. Monoclonal antibodies to complex antigens are notoriously difficult to prepare but recently two groups of workers have reported considerable success. Yoshida, Nussenzweig, Potocnjak, Nussenzweig & Aikawa (*Science* 207, 71; 1980), working in New York, have isolated monoclonal antibodies directed against a single protein on the sporozoites of *P. berghei* in mice. This protein, which has a molecular weight of 44,000, is found on no other stage of *P. berghei* nor on the sporozoites of *P. knowlesi* or *P. cynomolgi*. Further work in progress by these workers indicates that mice bearing hybridomas are resistant to challenge with *P. berghei* sporozoites. At the Wellcome Laboratories in England, Freeman, Trejdosiewicz & Cross (this issue of *Nature*, page 366) have fused myeloma cells with spleen cells from mice immune to *P. yoelii* and produced monoclonal antibodies against the parasites in 38 out of 143 cultures. Five of these lines were expanded, one against all the stages in the blood, two against merozoites and two against infected red cells. Sera from mice carrying hybridoma lines were then injected into mice with a rising virulent *P. yoelii* infection and those against the merozoites protected the recipients from death. These sera, however, did not prevent the development of a considerable parasitaemia and were not nearly as protective as hyperimmune sera from *P. yoelii* immune mice.

Both of these sets of experiments can be criticised on the grounds that the models chosen could have been closer to the human ones and the authors would no doubt be the first to agree that these are very preliminary results indeed. They do, however, make a quantum jump in our approach to malaria immunology for they demonstrate that it is possible to differentiate between antigens that are actually targets in the immune response and those that are irrelevant. There is nothing special about the mouse malaria models and these findings can easily be applied to primate and human malarias. The way is now open for the use of monoclonal antibodies to bind particular antigens on malaria parasites that can then be freed from the antibody and used in immunization studies. It is here that the

mouse malaria model will be of less use because it depends on the particular nature of the immune response of that host rather than on the nature of the parasite.

These experiments have not shown that sporozoite vaccination is any better than merozoite vaccination nor that antibodies act exclusively, or even mainly, on merozoites. Furthermore, the failure of monoclonal antibodies directed against malaria antigens on the red cells to protect mice means that the idea that such antigens may somehow be involved in protection will have to be reinvestigated. The way ahead is clear, though, and it should soon be possible to implicate particular characterized antigens in the protective immune response and also clarify our uncertain understanding of antigenic variation. We might now have an extremely useful tool but we are still a long, long way from a realistic and acceptable vaccine. □

Death and the neurone

from Julian Lewis

THE great problems of neural development express themselves in many small mysteries. Among these is the phenomenon of motoneurone death. Vertebrate embryos generate at first an excess of motoneurons, and 50% or more of the initial set normally die, round about the time when neuromuscular connections begin to form. Why are these surplus cells produced, and what causes their death?

The phenomena are well-documented for several systems, chiefly in birds and amphibians, including the spinal motoneurons that innervate the limbs, the trochlear motoneurons that innervate the superior oblique muscle of the eye, and the parasympathetic motoneurons of the ciliary ganglion, which innervate the intrinsic eye muscles (for a recent review see Jacobson *Developmental Neurobiology*, 2nd ed., Plenum, 1978). The extent of motoneurone death can be modified in various ways. For example, the embryonic rudiment of a limb, either of a bird or of an amphibian, can be cut off at an early stage, before it has become innervated. This does not upset the generation of normal numbers of motoneurons in the spinal cord, nor the initial outgrowth of their axons; but it prevents their survival. Almost all the cells which should have innervated the absent limb die, and they die at about the time when motoneurone death would normally occur. The interpretation seems obvious: motoneurons survive only in proportion to the quantity of target tissue; muscles will accept only a limited density of innervation, and death is the fate

of motoneurons which fail in a competition to form synapses (Hamburger *J. comp. Neurol.* **160**, 535; 1975). Individuals of a species vary in their bodily proportions. The normal surplus of motoneurons would guarantee that there would be enough to innervate even limbs that were disproportionately large; cell death would dispose of any excess. Thus the final number of motoneurons would be matched to the amount of muscle.

This tempting suggestion is supported to some extent by another experiment. When an additional limb is grafted onto an embryo, fewer of the motoneurons die. The number saved from death is, however, less than the extra limb might be expected to maintain (Hollyday & Hamburger *J. comp. Neurol.* **170**, 311; 1976; Lamb *J. Embryol. exp. Morphol.* **49**, 13; 1979). Studies of the chick ciliary ganglion give other grounds for caution. There too, about half the motoneurons die during normal development, and almost all die if the early eye rudiment has been removed. But the cells that die suffer different sorts of death in the two circumstances. The normal death involves, for example, a swelling of the cisternae of the endoplasmic reticulum without detachment of ribosomes from it, whereas the death by peripheral deprivation involves detachment of ribosome (Pilar & Landmesser *J. Cell Biol.* **68**, 339; 1976).

In this issue of *Nature* (page 347), Lamb gives strong direct evidence against the idea that normal motoneurone death is due to competition for a target that will accept only a limited density of innervation. Lamb amputates one hindlimb bud of a *Xenopus* tadpole, and manages to divert the nerves that should have innervated it into the remaining hindlimb, which is thus supplied from both sides of the spinal cord. The proportion of motoneurons that die in this case turns out to be practically the same as normal, so that the total number of survivors innervating the single remaining limb is twice as great as normal. There is no sign of competition between the motoneurons for a limited territory; the limb has parking space to spare.

Another popular interpretation of motoneurone death is that it serves to eliminate errors in the pattern of connections. This idea also has its problems. In the normal course of development, even the motoneurons that will die send axons out into the periphery and, in chicks at least, they appear to send them to the right places in the periphery. This can be shown by tracing projections with horseradish peroxidase. Particular muscles turn out to be innervated by pools of motoneurons lying in distinctive and reproducible positions in the spinal cord; in the chick, this pattern is accurately established before the period of motoneurone death, and changes hardly at all thereafter (Landmesser *J. Physiol. Lond.* **284**, 391; 1978) although in *Xenopus* the projections shift somewhat at

early stages (Lamb *Devl Biol.* **54**, 82; 1976).

The most intriguing clue to the puzzle of motoneurone death comes from experiments with toxins that block neuromuscular transmission (Pittman & Oppenheim *J. comp. Neurol.* **187**, 425; 1979; Laing & Prestige *J. Physiol. Lond.* **282**, 33; 1978; Creazzo & Sohal *Expl Neurol.* **66**, 135; 1979). One might be inclined to guess that such toxins should cause, if anything, increased death of motoneurons, mimicking the effect of absence of muscle. Precisely the opposite is observed: curare, α -bungarotoxin, α -cobratoxin and botulinum toxin, given in the period when motoneurons normally die, can all prevent the death. In this they are effective so long as movement is paralysed; when the concentration of toxin falls to the point where movements can begin, the surplus motoneurons belatedly die. The normally-occurring cell death evidently depends on neural activity. The phenomenon must therefore be closely linked with another little mystery of neural development, concerning spontaneous movement: why is it that vertebrate embryos start to writhe and squirm and wave their limbs about haphazardly as soon as neuromuscular connections have begun to form (Hamburger in *Behavioural Embryology*, vol. 1 (ed. Gottlieb) Academic Press, 1973)?

The activity of a motoneurone depends on the inputs which it receives in the spinal cord; and it is after all the set of conditions under which a neurone fires, not the location of its soma, that matters for the functioning of the system. If, abandoning the notion that motoneurons die in a competition for a limited quantity of target tissue, we espouse instead the theory that they die because they have made mistaken connections, we must suppose that the mistakes lie not in the relation between the position of the soma and the choice of target muscle, but rather in the relation between the choice of target muscle and the set of central inputs to the motoneurone. A simple speculation along these lines might be that some motoneurons die because they are, in their time of firing, out of step with their fellows in a pool of motoneurons innervating a single muscle; they might feel the effects at their point of contact with that muscle, during periods of muscle stimulation. From a very early stage, there are indeed correlations in time of firing between pools of motoneurons innervating different muscles, and these become sharper as development proceeds (Bekoff, Stein & Hamburger *Proc. natn. Acad. Sci. U.S.A.* **72**, 1245; 1975; Bekoff *Brain Res.* **106**, 271; 1976). But again, the speculation encounters difficulties. It would suggest, for example, that where there is less scope for mistakes, there should be less death: that in a nucleus such as that of the trochlear nerve, which innervates only one muscle, there should be no confusion of connections, and all the motoneurons should survive. But they

don't. In the trochlear nucleus of a bird, just as in the ventral horn of its spinal cord, half the motoneurons die (Cowan in *Development and Aging of the Nervous System* (ed. Rockstein), Academic Press, 1973).

The evidence so far has not yielded a solution to the puzzle of motoneurone death; but it has at least proved that the solution will be interesting. □

Birds see ultraviolet light

from J.K. Bowmaker

HUMAN colour vision extends from about 400 nm in the violet to about 750 nm in the red. Why are we restricted to this limited range? About 80% of the electromagnetic radiation reaching the Earth's surface lies between 300 nm in the ultraviolet and 1,100 nm in the infrared, but nevertheless only part of this spectrum is available for vision since radiation with wavelengths longer than about 800 nm has too little energy to cause photochemical reactions. Thus there is available for vision a spectral range from about 300 nm to 800 nm. However, the limits of an animal's vision are determined by the visual pigments contained within the photopic receptors of the retina, the cones, and by pre-receptor filters. In man these are principally the lens that cuts off light below about 400 nm, and the macula pigment in the yellow spot of the retina. Filtering violet and near ultraviolet light reduces chromatic aberration which becomes increasingly severe at short wavelengths.

The question remains whether other species are similarly restricted. It is natural perhaps to compare the visual sense of other diurnal species with our own, on the assumption that we represent the culmination of the evolution of colour vision. But is this reasonable? The early mammals, around at the time of the dinosaurs, were probably nocturnal, resulting in their colour vision becoming largely degenerate, with many modern mammals having only limited dichromatic vision. The Old World primates, including man, are somewhat of an exception in that they have evolved secondarily trichromatic vision along with the adoption of diurnal habits. Even so our trichromacy has a 'blue' channel that is about 100 times less sensitive than the 'red' and 'green' channels. The true culmination of the evolution of colour vision in vertebrates would be expected to be found in highly evolved diurnal animals, perhaps best represented by diurnal birds and it is

within these species that we should look for colour vision making use of more of the available spectrum.

The most striking feature of the retina of diurnal birds is the presence of brightly coloured oil droplets contained within the cones that act as highly selective long-pass cut-off filters (see Bowmaker *Vision Res.* 17; 1129; 1979). The lenses of most diurnal birds are optically clear and it seems that one of the functions of the oil droplets is to limit chromatic aberration selectively at the receptor level. However, amongst the coloured oil droplets there are colourless ones that presumably transmit near ultraviolet light with the possibility that diurnal birds can detect these short wavelengths as a 'colour', different in hue from the rest of their visible spectrum.

It is known that pigeons can see in this spectral region (Wright *J. exp. anal. Behav.* 17, 325; 1972) and in a recent paper Timothy Goldsmith (*Science* 207, 786; 1980) has presented evidence that several species of humming bird can discriminate the near ultraviolet. Working with a natural population of the birds he set them a simple task of selecting artificial feeders containing a sugar solution on the basis of a coloured viewing screen set in the feeders. The birds were able to distinguish the near ultraviolet around 370 nm from darkness or from the small amount of far red light that leaked through the ultraviolet transmitting glass filter, which human observers were unable to do. The birds could also distinguish white light lacking wavelengths below 400 nm from white light from a quartz-halogen bulb that does contain near ultraviolet radiation.

The near ultraviolet sensitivity of the humming birds presumably involves cones containing an oil droplet that transmits short wavelengths but also a visual pigment that is sensitive to these wavelengths. Evidence from pigeons and chickens (Graf & Norren *Vision Res.* 14; 1203; 1974) indicates that in addition to red, green and blue-sensitive visual pigments there is a visual pigment with maximum sensitivity at about 400–415 nm. This is very close to the maximum sensitivity of the visual pigment of human 'blue' cones (415–420 nm) recently recorded by Bowmaker and Dartnall (*J. Physiol. Lond.* 298, 501; 1980), but the effective maximum sensitivity of the human cones is displaced to about 440 nm with a marked cut off below about 400 nm due to the filtering of the lens.

The other major group of animals known to have vision in the ultraviolet are the insects. Here chromatic aberration is not a problem since arthropod eyes are designed on different optical principles. These insects, principally bees and moths, have mouthparts designed to suck nectar from flowers, and many of the flowers rely on their insect visitors for pollination. Many such flowers reveal striking patterns of 'nectar guides' if photographed using ultraviolet sensitive film that are not visible

to a human observer and it is assumed that the evolution of such guides has paralleled the evolution of ultraviolet vision in these pollinating insects. It would be interesting to know whether the flowers usually frequented by humming birds have similar ultraviolet nectar guides. However, as Goldsmith says "the interplay of several spectral classes of oil droplet with several cone pigments and the presence of receptors functioning in the near UV suggests that avian colour vision possesses a richness beyond our ken". □

BL Lacertae Objects —the 'missing link'?

from a Correspondent

A RECENT study of a sample of extragalactic radio sources belonging to the so-called BL Lacertae class has shed some new light on one of the most interesting questions in extragalactic radio astronomy, namely the relationship between the radio sources associated with galaxies and those associated with quasars.

Until 1968 the optical objects found to be associated with extragalactic radio sources could be divided into two basic classes, galaxies and quasars. The galaxies have a variety of forms, basically appearing diffuse on photographs; their optical spectra are also varied, ranging from the thermal continua and weak absorption lines typical of old stars to the non-thermal continua and strong emission lines which are indicative of violent activity in the galactic nucleus. This latter type of spectrum is also typical of the quasar which appear starlike on photographs and are generally at higher redshifts than the galaxies. In 1968 an apparently new class of identification was found when the radio source VRO 42.22.01 was identified with the so-called 'variable star' BL Lacertae. The radio source itself was very unusual showing striking, rapid variations in radio flux density and in polarization. In this respect it bore similarities to the very compact sources associated with some quasars though its variations were more extreme. However, the optical spectrum of the 'star' was apparently completely featureless showing neither emission nor absorption lines, the continuum being clearly non-thermal in origin; the optical radiation was also strongly polarized and very variable in intensity. The absence of lines in the spectrum made this very peculiar object particularly tantalizing as there was no means by which to determine its redshift and its distance.

Subsequently many more sources of this type, now called BL Lac objects, have been found and to date roughly 60 are known.

J.K. Bowmaker is a Lecturer in the Department of Zoology and Comparative Physiology, Queen Mary College, London

The defining properties of the objects in this class are that their optical spectra have steep non-thermal continua with no strong emission features, there is rapid variability at optical, radio and infrared wavelengths, and there is strong and rapidly varying polarization. The objects vary quite widely in optical appearance, ranging from those which are completely stellar to those which are the nuclei of galaxies. Though it was originally thought that the optical spectra were completely featureless, careful spectroscopic work on some of these objects, particularly BL Lac itself, has revealed weak emission and absorption features similar to those found in elliptical galaxies, so that it has been possible to determine the distances and physical properties in some cases. It is now possible therefore to compare their physical properties with those of quasars and radio galaxies and to investigate their relationship to these objects.

Such an investigation has been carried out by Weiler & Johnston (*Mon. Not. R. astr. Soc.* 190, 269; 1980) who have made a detailed radio study of a large sample of BL Lac objects, examining their radio structures on scales ranging from a few thousandths of an arc second to arc minutes. Their results indicate that the majority of the BL Lac objects contain very compact cores with at least half of the total flux density and with properties very similar to the compact variable quasars. However they also find that over half of them have extended radio emission as well, with sizes and luminosities comparable with those of the extended sources associated with radio galaxies and quasars; the BL Lac objects are thus apparently indistinguishable from the radio galaxies and quasars on the basis of their radio structures. Furthermore, as the luminosities of their compact radio cores span the whole range from the relatively weak cores seen in radio galaxies to the stronger ones in quasars, they seem to form a 'link' between the quasars and radio galaxies. Further evidence of such a link comes from the fact that the BL Lac objects appear to occupy an area intermediate between that covered by quasars and that occupied by radio galaxies on a radio flux density-optical magnitude diagram.

It thus seems possible that the BL Lac objects represent a transition phase between quasars and radio galaxies. Weiler and Johnston speculate that a radio quasar may represent the early stages in the evolution of an elliptical galaxy which contains a significant amount of gas in its central regions; this gas, as well as producing the observed emission lines, is used in some way to power the central 'engine' which is responsible for the violent radio and optical activity. If this gas is used up or expelled the emission lines will disappear and the operation of the engine may become more variable, so that the quasar may evolve into a BL Lac object.

Finally as all the gas is used up, the activity may decrease still further leaving the relatively weak core sources seen in most radio galaxies.

Although this evolutionary sequence is not the only interpretation of the results it is certainly an interesting possibility. There is much scope for further work to clarify the situation. It is important to determine the space densities of the BL Lac objects to test that these are consistent on the basis of the evolutionary sequence with the already known space densities of quasars and radio galaxies. However, this analysis may be difficult if only because unambiguous selection of a sample of BL Lac objects is almost impossible as a result of the degeneration in the definition of their properties and the continuity of these properties with those of radio galaxies and quasars. More insight is likely to be gained from detailed information on the radio structures of the BL Lac objects on all angular scales; in particular comparison of the structures of the BL Lac cores with those of radio galaxies and quasars on milliarcsecond scales will be particularly revealing as it is these core sources that provide perhaps the strongest evidence for the evolutionary sequence. □

Towards the ideal seismic experiment

from Bob Whitmarsh

THE most powerful remote sensing technique used in the search for hydrocarbons is seismic reflection. Carefully controlled sources radiate acoustic energy which is reflected from sub-surface interfaces and sensed by a large number of transducers usually arranged in a linear array relatively close to, and aligned with, the source. Subsequently complex and highly sophisticated signal processing techniques are applied to the recorded signals to increase the depth range or penetration of the final reflection profile as well as its vertical and horizontal resolution. The ultimate objective of the reflection technique is to translate the observed vertical reflection times from different strata into depths and this requires a knowledge of seismic velocities in the overlying layers. During a normal reflection survey the accuracy of the velocity determinations is limited, particularly for deeper reflectors, by the length of the receiving array. This length determines the range of incident angles at the reflector for the group of rays from a single shot.

More accurate information about the deeper velocity structure can be obtained if

the distance between source and receiver is steadily changed and this type of experiment, radically different from normal reflection profiling, can be used to study reflections from vertical incidence out to the ranges where critical reflection occurs and beyond. At sea, until recently, such variable angle reflection experiments have mostly been carried out using one or more free-drifting surface sonobuoys or fixed ocean-bottom seismographs. The optimum procedure for reflection studies however is to use a source and receiver which move with equal but opposite velocities away from a fixed point (the common depth point (CDP)). Then all the reflections picked up by a towed array from a given interface originate at the same fixed area on the interface irrespective of the incident angle thereby avoiding the difficulties due to irregular interfaces. At sea the only practical solution is to use two ships, it being a great advantage if one of these is fitted with a multichannel hydrophone array. This is the procedure recently reported by Stoffa & Buhl (*J. geophys. Res.* 84, 7645; 1979) which they have used to carry out a series of deep crustal studies of oceanic areas.

The first description of a two-ship multichannel seismic experiment to study oceanic crust seems to have been that of Limond *et al.* (*Earth planet. Sci. Lett.* 15, 361; 1972). They fired a 34-km long expanding spread profile (ESP) in the Bay of Biscay. Shots fired every 800 m were received by a 2.4 km long 24-channel array thereby providing three-fold coverage. As the object was to obtain Moho reflections on the multichannel reflection profile (these were identified by working back from Moho refracted arrivals through sub-critical reflections to vertical incidence) the signal processing of the seismic traces did not proceed beyond the presentation of a record section.

The experiments of Stoffa and Buhl however were specifically designed to study the deep oceanic crust with the greatest practical precision. In such experiments both horizontal range and shot-to-receiver travel time need to be determined to within a few tens of metres and a few milliseconds respectively. Ideally, precise absolute navigation is required so that the two ships lie symmetrically about the common depth point at all times. In practice, even though the relative navigation of the ships is correct, as can be established using a ship-to-ship radio ranging system, surface currents (which may not be detectable during the experiment) can introduce important errors. Such errors probably exceed those due to dipping reflectors. Their combined effect tends to invalidate the basic assumption underlying CDP but fortunately does not necessarily negate the usefulness of ESP experiments. Except in nearshore areas covered by high quality radio-navigation systems there is at present no simple practical solution to this navi-

Bob Whitmarsh is at the Institute of Oceanographic Sciences, Wormley.

gational problem. The timing precision is easier to obtain, particularly with electrically fired airguns or explosions.

In recent years advances in marine seismic work have come more from new methods of quantitative analysis and numerical modelling than of experimental technique. An example of such an analytical method is that used by Stoffa and Buhl to extract phase velocity information from the record sections. This is done on a shot by shot basis using a semblance technique to determine the phase velocity having the greatest coherence across each set of 24 traces beginning in turn at each successive digitised sample along the nearest or first trace. The technique is useful in that it enables over-lapping or 'crossing-over' signals of different phase velocity to be separated as well as giving an objective assessment of the onset times of second arrivals which might otherwise have been picked too late. From analysis of the semblance plots a precise travel time *versus* distance plot is produced for all arrivals whose semblance coefficient exceeds a given value, and this plot in turn is inverted using a derivation of a standard method to give a highly detailed velocity/depth profile of the oceanic crust.

A disadvantage of the ESP method outlined above is that the structure under each shot and receiver position may differ, whereas for a fixed ocean-bottom seismograph at least half this possible lateral variation is avoided. However some indication of lateral velocity inhomogeneity can be obtained, again using two ships, by keeping the source and receiver at a fixed distance (constant offset profile or COP) appropriate to the interface of interest. By combining COPs having different offset distances with CDP and normal multichannel reflection profiles it is possible to approach the ideal deep crustal seismic experiment. However to model the Earth fully taking account of all the constraints provided by these types of observations is probably taking the problem beyond the scope of the best computer facilities.

The technique described by Stoffa and Buhl opens up exciting possibilities for detailed deep crustal studies in the oceans. In practice however it is unlikely that there will be many researchers in a position to follow their example. Regrettably, multi-channel digital recording systems, digital seismic reflection processing and two-ship experiments are expensive. But such experiments might continue perhaps on an inter-institution basis in areas of mutual scientific interest. Continental margins in particular, where the results could be of more than academic interest and where two-ship experiments are more likely to obtain the necessary funding would provide attractive targets. Such an approach has already led to a joint French-United Kingdom study of the margin southwest of the English Channel last year.

Recent advances in polarized electron sources

IN his article "Polarized electrons are going around in circles" (*News & Views* 283, 248; 1980) C.B. Lucas notes that recent advances in sources of polarized electrons should provide insights into fields as diverse as neutral currents, surface physics, and molecular optical activity. He calls attention to recent developments in atomic physics-based polarized electron sources and to the fact that beams of electrons and positrons become polarized as they circulate in a storage ring. We would like to describe some very recent advances that have been made in the development and application of solid state sources of polarized electrons.

Extraction of electrons from a ferromagnetic solid offers a conceptually elegant source of polarized electrons. The electrons are aligned by an external magnetic field and exist in densities unobtainable in aligned atom beams. A very useful source has been demonstrated¹ using field emission from a tungsten tip that has been coated with europium sulphide. At the operating temperature of 10 K, the EuS is ferromagnetic and acts as a spin filter. A polarization of 0.85 is obtained at currents up to 10 nA. Most notably, the source has very high electron optical brightness and will be useful in applications requiring highly collimated, highly focused beams.

The most recently developed² solid state source of polarized electrons uses photoemission from gallium arsenide. When GaAs is irradiated with circularly polarized light, the electrons excited from the maximum of the spin-orbit-split valence band may be polarized up to a theoretical value of 50%. GaAs is one of those special materials in which, by application of caesium and oxygen to the surface, the vacuum level can be lowered below the bulk conduction band minimum to produce the so-called 'negative electron affinity' emitter. Negative electron affinity GaAs is not only an extremely efficient photoemitter but the electrons can be polarized! When the light is modulated from right to left circular polarization, the direction of the polarization of the electron beam is also modulated, facilitating the use of very sensitive signal detection techniques.

A source of polarized electrons utilizing GaAs has been built which produces a continuous beam with a polarization of $\pm 43\%$, and a beam

current of 20 μA has been obtained for one milliwatt of incident circularly polarized light². A pulsed GaAs source has produced microsecond pulses of several hundred milliamperes at a 120 Hz repetition rate³.

In a sense, the GaAs source is the solid state analogue of the source utilizing the 'Fano effect' in caesium discussed by Lucas. The higher density of the solid provides much more intense electron beams; typically three orders of magnitude more intense than existing Fano effect sources. The energy spread of the GaAs source is 130 meV FWHM, and the effective source area is determined by the focus of the circularly polarized light, typically 0.5 mm diameter. The electron optical brightness is second only to the EuS/W field emission source.

The Fano effect in Cs can produce electron beams nearly 100% polarized. In most experiments the lower polarization of the GaAs source is easily compensated by increasing the intensity of the beam, but there are experiments, for example, where target damage is a problem, where higher polarization is required. There is hope of increasing the polarization of the GaAs source by lifting the degeneracy at the valence band maximum by (1) stressing the crystal (2) preparing epitaxially grown multilayer structures to confine the electron in one-dimensional potential wells, or by using (3) crystal field splitting in chalcopyrite semiconductors such as CdSiAs_2 or CdGeP_2 , which are ternary analogues to GaAs.

The GaAs source has already been very effectively applied at SLAC to measure the parity non-conservation in inelastic scattering of 20 GeV polarized electrons from hydrogen and deuterium³. It has been used to observe the surface magnetization of ferromagnetic nickel through the exchange interaction in low energy polarized electron scattering experiments⁴. It has also been used in polarized electron diffraction studies of single crystal tungsten⁵. The recent demonstrations of the characteristics of this type of source have led to the construction of such devices by nearly every group engaged in polarized electron scattering.

We agree completely with Lucas that there are now many exciting research opportunities because of recent advances in polarized electron sources. We believe that the new solid state source technology will play a significant part.

ARTICLES

The narrow rings of Jupiter, Saturn and Uranus

S. F. Dermott

Recent occultation studies and spacecraft observations have revealed the presence of narrow ring systems around the planets Jupiter, Saturn and Uranus. Thus three of the four major planets are now known to contain systems of narrow rings. This article attempts to account for the origin and location of these rings.

OUR knowledge of the uranian rings is extensive and it is possible to list a large number of features which any theory of narrow rings ought to be able to account for (see ref. 1). We know little about the jovian ring system at present, apart from its location and the fact that the outer ring is only 6,000 km wide². This ring contains a bright inner ring of width 800 ± 100 km (ref. 2). Voyager 2 images have revealed the presence of a small, dark satellite of diameter between 20 and 40 km with an albedo ~ 0.05 (refs 3, 4). The orbit of this satellite lies in the ring plane and appears to define the outer edge of the rings as seen by reflected light (ref. 4 and G. E. Danielson, personal communication).

Pioneer 11 detected at least one comparatively narrow saturnian ring and possibly several small satellites, some of which may orbit within the rings^{5,6}. The radial width of the F-ring discovered by the Pioneer 11 imaging team⁶ is not greater than 800 km (ref. 6). The 3,500-km gap between this ring and the broad A-ring (the Pioneer gap) contains less material than Cassini's division⁶. The Pioneer 11 Geiger tube team⁵ detected a possible ring of width 3,600 km between 2.550 and $2.490 R_s$ ($R_s = 60,000$ km is the equatorial radius of Saturn) which may contain two satellites of diameter ≥ 170 km at 2.534 and $2.522 R_s$. They also detected a ring (F) of width 2,100 km between 2.371 and $2.336 R_s$, which may contain two satellites at 2.343 and $2.350 R_s$, and a possible new satellite at $2.82 R_s$. The fact that the two determinations of the width of the F-ring are quite different suggests that the ring is wide ($\sim 2,100$ km) but, like the jovian ring, contains a bright inner ring of width ~ 800 km.

It is well known that the 2:1 Mimas resonance lies close to the outer edge of the B-ring⁷. We point out here that the 3:2 Mimas resonance ($2.361 R_s$) lies close to the outer edge of the F-ring ($2.371 R_s$) and that the 4:3 Mimas resonance ($2.553 R_s$) lies close to the orbits of the newly discovered satellite or satellites at 2.534 and $2.522 R_s$. These calculations assume that the coefficient of the principal gravitational harmonic $J_2 = 0.01667$ (ref. 9) but neglect the mass of the rings since this is not known.

Dermott *et al.*¹ consider that the extremely narrow widths and sharply defined edges of the uranian rings imply that some kind of critical phenomenon is responsible. They suppose that each ring contains a small satellite which maintains solid particles in stable, horseshoe orbits about its lagrangian equilibrium points (see Fig. 1). They show that this model explains most of the observed features of the uranian rings. By comparison Goldreich and Tremaine⁸ suggest that each ring consists of particles confined between the orbits of two small satellites.

They show that this theory can explain how the particles can remain in precisely aligned elliptical orbits but they do not explain other features of the rings, such as sharp edges and the narrow range of widths of the rings.

The uranian and jovian ring systems, both of which are comparatively narrow, have mean orbital radii of 1.8 planetary radii. We consider it significant that both systems also lie in the Roche 'zone' defined by Dermott *et al.*¹ (see Figs 2 and 3). The location of the narrow jovian ring suggests an origin similar to that of the uranian rings. Whether this ring consists of a number, possibly a large number, of discrete rings or whether it is continuous is not yet known. We suggest that the jovian ring is the product of the disintegration of a satellite that entered the Roche zone, probably as a result of orbital evolution due to tidal dissipation, and that large numbers of small particles are now maintained in horseshoe orbits about the lagrangian equilibrium points of the remanent chunks. The recent observation of a small satellite in the outer edge of the rings supports this view. Collisional, as well as tidal processes were probably involved in

Fig. 1 Dermott *et al.*¹ suggest that each uranian ring contains a small satellite which maintains particles in stable, horseshoe orbits about its lagrangian equilibrium points. In their model, loose solid particles leave the satellite surface and enter orbits closely similar to that of the satellite (which can be both eccentric and inclined to the equatorial plane of the planet). It is the gravitational force of the satellite in a resonance with the ring particles which then provides the critical phenomenon needed to define a narrow, sharp-edged, asymmetric ring.

* Present address: Center for Radiophysics and Space Research, Space Sciences Building, Cornell University, Ithaca, New York 14853.

Fig. 2 Roche limit a_L for Uranus as a function of satellite density. a_L (hydrostatic) applies to a satellite that can relax to hydrostatic equilibrium and a_L (spherical) applies to a spherical satellite. Dermott *et al.*¹ refer to the zone between these two extremes as the Roche zone. It is in this zone that a satellite is expected to lose solid particles from its surface. The location of the synchronous orbit shown above is based on the rotational period of 12.8 ± 1.7 h obtained from occultation data by Elliot *et al.*¹⁰.

the break-up of the original satellite. The positions of the rings with respect to the Roche zones and the synchronous orbits suggest that the jovian ring satellites have densities $\geq 3 \text{ g cm}^{-3}$ and that the uranian ring satellites have densities $\geq 2 \text{ g cm}^{-3}$. Most of Saturn's broad ring system and the newly discovered narrow rings lie above its synchronous orbit, hence the mechanism of ring formation discussed above cannot be applied.

Particle paths

The path of a ring particle when the orbit of the ring satellite is circular can be studied by considering the Jacobi integral. For motion in horseshoe orbits it is convenient to write the Jacobi constant C as¹¹

$$C = 3 + \alpha m^{2/3} \quad (1)$$

where m is the satellite-planet mass ratio. We have found, by numerical integration of particular cases, that the type of path followed by a particle depends on the value of α . If we write

$$a_i = 1 + \Delta a_i \quad (i = 0, 1, 2) \quad (2)$$

and

$$|\Delta a_0| - |\Delta a_j| = \pm m^n \quad (j = 1, 2) \quad (3)$$

where a is the semimajor axis of the particle and the subscripts refer to the number of consecutive encounters with the ring satellite that the particle has experienced, then we find that n varies with α and that n increases to values near unity as α tends to zero. Our results for $m = 10^{-9}$ are shown in Fig. 4. We also conclude from these experiments that motion in a horseshoe is

unlikely if α exceeds about 1.2. The existence of this limit may account for the sharp edges of the rings.

For motion in a circle

$$\Delta a = 2 \left(\frac{\alpha}{3} \right)^{1/2} m^{1/3} \quad (4)$$

Thus the width of the ring is proportional to $m^{1/3}$ and a wide range of satellite masses produces a comparatively narrow range of ring widths. This could account for the observation that the uranian rings have a small spread of widths.

For small values of α (≤ 0.3), the changes in a on encounter are such that Δa_0 and Δa_1 are almost exactly equal and opposite. If we write

$$\delta a = (|\Delta a_0| - |\Delta a_1|) / \Delta a_0 \quad (5)$$

then

$$\delta a \sim \pm m^{n-1/3} \quad (6)$$

and, for $\alpha \leq 0.3$, $n \geq 2/3$ and $|\delta a| \sim m^{1/3}$. Thus, for $m \leq 10^{-9}$ (10^{-9} is greater than the satellite masses needed to account for the widths of the uranian rings) $|\delta a| \lesssim 10^{-3}$ and

$$\Delta a_0 = -\Delta a_1 \quad (7)$$

to 1 part in 10^3 or greater (see Fig. 5). It is this symmetry which accounts for the peculiar stability of very narrow rings.

This symmetry is not a property of the circular orbit case alone. If the ring satellite has an eccentric orbit, and if Δa_0 or α is small and e_0 and e_s , where subscript s refers to the ring-satellite, are not too different, then the changes in a on encounter are still symmetrical. Here, we define α by equation (4) even though the Jacobi integral does not apply to the eccentric orbit case. Our results for $m = 10^{-9}$ and $e_s = 0.01$ (which is close to the mean eccentricity of the uranian ϵ ring) are shown in Fig. 4. There seems to be no substantial difference between the circular orbit and the eccentric orbit cases.

Fig. 3 Roche limit for Jupiter as a function of satellite density. Note the similarity between the location of the rings on this figure and those in Fig. 2.

Fig. 4 n is a measure of the symmetry of the horseshoe path about the line $a = 1$ (see equation (3) and Fig. 5). The circular points refer to changes in the semimajor axis a of the ring particle orbit after a single encounter with the ring-satellite: ●, the circular orbit case ($e_s = 0$, where e_s is the eccentricity of the ring-satellite orbit); ○, the elliptical orbit case ($e_s = 0.01$). Triangles indicate the total change in a after two consecutive encounters: ▲, the circular orbit case ($e_s = 0$); △, the elliptical orbit case ($e_s = 0.01$).

The effect on the orbit of a ring particle of an external force due, for example, to Poynting–Robertson light drag is shown in Fig. 5. If α is small (≤ 0.3), then Δa_0 and Δa_1 are always equal and opposite: drag forces have little influence on this phenomenon. Therefore, if the ring is very narrow and the magnitudes of the drag forces acting on the particle on the inside and on the outside of its horseshoe path are not too different, then the orbital decay achieved in one half of the path is, in effect, cancelled by that achieved in the other. Second order effects due to the finite width of the ring are very small and we will not discuss them here.

As the drag force extracts angular momentum from the ring system, some orbital decay must occur. But the orbits of the ring particles and the ring satellite decay together at some rate r times less than that of an unconstrained ring particle.

$$r \sim \frac{m_r}{m + m_r} \quad (8)$$

where m_r is the total mass of the ring particles. For a ring of optical depth unity,

$$r \sim 5 \times 10^{-4} \left(\frac{a}{50,000 \text{ km}} \right) \left(\frac{d}{0.1 \text{ cm}} \right) \left(\frac{10 \text{ km}}{W} \right)^2 \quad (9)$$

where W is the mean width of the ring. Thus, even if the rings of Uranus consist of very small particles ($d \ll 0.1 \text{ cm}$), Poynting–Robertson drag acting over times comparable with the age of the Solar System would not result in significant orbital decay or ring spreading.

Radiation pressure acting on small (micrometre size) particles in an optically thin ring could distort the particle paths and, in the case of the jovian ring, the discussion we have given in terms of simple horseshoes may not be appropriate for these very small particles (J. A. Burns, personal communication). However, we contend that the presence of small satellites in the jovian ring is needed not only to provide a localised source of ring material,

but also to account for the partial confinement of the ring particles in a comparatively narrow lane.

Ring geometry

The remarkable variation in width of the uranian ϵ ring is a consequence of the ring's large eccentricity gradient $g(= a \, de/da)$. The ratio w of the maximum and minimum ring widths is given by¹

$$w = \frac{1+g}{1-g} \quad (10)$$

The mean ring width is $2\Delta a$, where Δa is half the difference of the semimajor axes of the ring's inner and outer edges. Since w must be positive, we must have $g < 1$. For the uranian ϵ ring $\Delta a = 30 \text{ km}$ and $g = 0.62$ (ref. 12). Thus, g is not merely non-zero, it is also close to the critical value of unity. Accounting for this phenomenon is by far the largest hurdle that any theory of the rings of Uranus has to surmount.

If a ring has a uniform eccentricity gradient and the particles in the ring have a common pericentre, then the relative velocities at pericentre are very much less than those at apocentre. We consider that it is probably this asymmetry which gives rise to the systematic changes in the orbital elements of the ring particles on encounter with the ring satellite.

Some actual changes in the orbital elements produced by encounter are shown in Fig. 6. The parameters chosen for this particular numerical experiment were $\alpha = 1.2$, which is the critical value of α for horseshoe motion, $m = 10^{-10}$ and $e_s = 0.00780$, which is the mean eccentricity of the uranian ϵ ring. If $a = 51,284 \text{ km}$, which is the mean semimajor axis of the uranian ϵ ring, then these parameters give $W = 2\Delta a = 60 \text{ km}$, which is the observed mean width of the ring. The values of a_s , e_s , a_0 and e_0 were dictated by the observed eccentricity and eccentricity gradient of the ϵ ring. Thus, particles on the outside of the ring were given values $e_0 = 0.00816$ and those on the inside values $e_0 = 0.00744$. The initial phases of the particles with respect to the satellite were chosen randomly with approximately equal numbers on the inside and on the outside of the ring.

The histogram of the values of g produced by this experiment (see Fig. 6) shows a strong positive bias with a peak at $g \approx 0.5$, which is close to the gradient ($g = 0.62$) defined by the edges of the ϵ ring. However, many factors will have an influence on this experiment. These include α , m , and, in particular, the shape of the satellite. These factors have yet to be investigated in detail. It would appear that the horseshoe orbit model of Dermott *et al.*¹ may account for the observed eccentricity gradient of the uranian ϵ ring, but we do not regard this question as settled. However, we have confirmed that the changes in pericentre $\tilde{\omega}$ of the ring particle orbit on encounter are small ($\leq 2^\circ$). Hence, as particles in horseshoe orbits spend equal amounts of time on the

Fig. 5 Path of a particle moving in a horseshoe orbit about a ring-satellite of mass $m = 10^{-9}$ (circular orbit case). Semimajor axis a is plotted against the angular separation θ of the particle and the satellite. The dashed line refers to the particle path in the absence of drag and the solid line shows the effect of an external drag force. Both paths are symmetrical about the line $a = 1$.

Fig. 6 Histogram showing the changes in eccentricities and semimajor axes produced by encounter with a ring-satellite in an eccentric orbit ($e_s = 0.00780$). The initial phases of the particles with respect to the satellite were chosen randomly. The strong positive bias in the distribution of $g = (e_0 - e_1)/(a_0 - a_1)$, where the subscripts 0 and 1 refer to values before and after encounter) could account for the observed eccentricity gradient ($= 0.62$) and hence the variation in width of the uranian ϵ ring.

inside and the outside of the ring, their average precession rate equals that of the ring-satellite and differential precession associated with the oblateness of the planet does not result in ring spreading. The pericentres of the ring particles remain aligned.

Stability

Even in the absence of drag, the particle path shown in Fig. 5 is not closed, since after every second encounter of a particle and the ring-satellite $|\Delta a|$ has changed in total by some small amount $\sim \pm m^n$ (see equation (3)). This suggests that the evolution of $|\Delta a|$ can be described by a random walk process and, since $n \leq 1$, that a particle will be lost from the ring after $\leq (1/2 W/m)^2$ encounters. The time between encounters is $2/3 \Delta a^{-1}$. From equation (4) we have

$$1/2 W \approx m^{1/3} \quad (11)$$

Hence, the lifetime of a ring particle is

$$\Gamma \approx \frac{T}{m^{5/3}} \quad (12)$$

where T is the orbital period of the ring satellite in arbitrary units.

Paradoxically, Γ increases as the mass of the ring satellite decreases: very narrow rings are particularly stable. For the Jupiter-Sun system $m \sim 10^{-3}$ and $T \approx 12$ yr; hence $\Gamma \sim 10^6$ yr and the lifetime of a ring orbiting the Sun with Jupiter would be short. It is probably significant that none of the Trojan asteroids are observed to have horseshoe paths. For a planetary ring, $T \sim 10^{-3}$ yr and if $m < 10^{-9}$, and this is greater than the masses needed to account for the widths of the uranian rings, then $\Gamma > 10^{12}$ yr.

Γ is not simply the lifetime of the ring, it must also be the time needed by a planet or satellite to sweep up small particles from its own orbit. If $T \sim 10^{-3}$ yr and $m < 2 \cdot 10^{-8}$, then $\Gamma > 5 \times 10^9$ yr. This suggests that very small satellites in the Solar System, which have not been captured and which lie outside the Roche zone, may be associated with narrow rings of primordial material that they have yet to accrete. We suggest that this could account for the newly discovered rings of Saturn. A ring of width ≤ 500 km

and radius 140,000 km would need only a satellite of mass $\leq 6 \times 10^{-9}$ (and diameter ≤ 200 km) to stabilise it. Such a ring would have a lifetime $\Gamma \geq 5 \times 10^{10}$ yr.

Discussion

The location of narrow rings and satellites just inside the Mimas first-order resonances supports the suggestion of Goldreich and Tremaine^{7,13} that these locations could be sites of preferential satellite formation. The observations are consistent with their theory that Mimas excited trailing spiral density waves in a disk of particles surrounding the planet at the positions of the $(p+1):p$ resonances (p is an integer) and that this resulted in the transfer of material towards the planet. Inside the Roche zone, this transfer of material has probably produced Cassini's and other divisions, the inner edges of which are associated with first-order resonances^{7,13}. We suggest here that outside the Roche zone this mechanism has resulted in satellite formation and that these small satellites maintain rings of particles they have yet to accrete.

Van Allen *et al.*⁵ claim to have detected possibly two satellites in the F ring and several small satellites outside this ring. Yet the probability of detecting a single, small satellite by their method is as low as $\sim 1\%$. In the 'ring' which they initially named the G-ring (2.490 to 2.550 R_s), both of these supposed satellites have diameters ≥ 170 km, but the separation of their orbits is only ~ 720 km (ref. 5). We suggest that their results could equally be accounted for by an eccentric ring of particles of width ≥ 170 km which is maintained by a single satellite of diameter ~ 45 km moving in an orbit of eccentricity ~ 0.005 . Similarly, the structure observed in the F-ring profile, which could be due to two satellites whose orbits are separated by only 420 km, could equally be accounted for by a ring of particles maintained by a single satellite moving in an orbit of eccentricity ~ 0.003 . Alternatively, the F and G rings could consist of a number of discrete narrow rings maintained by an equal number of small satellites. Both of these suggestions are less improbable than the suggestion of Van Allen *et al.*⁵ that on five separate occasions the Pioneer 11 spacecraft passed within a few degrees of the longitude of a small satellite.

Finally, if small satellites do exist inside the outer edges of the F and G rings, then the fact that the present orbit of Mimas is associated with the outer edges of these rings could place severe limits on changes in Mimas' orbit since the time of satellite formation. This conclusion could have profound implications with respect to the origin of resonances and the formation of satellites in the Solar System and the long-term stability of satellite orbits.

We thank T. Gold and I. P. Williams for useful discussions. S.F.D. thanks the SRC for the award of a Senior Visiting Fellowship. C.D.M. thanks the Northern Ireland Department of Education for the award of a studentship. This work was supported by NSF grant AST 79164-74-A01 and NASA grant NGS 7593.

Note added in proof: This article was written before the publication of the Pioneer 11 results in *Science*, 25 January 1980, and at the time we were not aware of the results of J. A. Simpson *et al.*¹⁴. They report that the distribution of matter in the F-ring is markedly non-uniform: the electron absorption features exhibit large radial and azimuthal variations. This supports our suggestion that the F-ring contains a number of small satellites, moving in elliptical orbits, which maintain narrow rings of particles of non-uniform width. They also report the detection of material distant 3.07 R_s from Saturn and close to the orbit of Mimas. But since the spacecraft was actually 0.04 R_s outside the orbit of Mimas at the time of the observation, we conclude that this material cannot be part of a narrow ring of the type we have described. However, since Mimas was $\sim 50^\circ$ ahead of the spacecraft at the time, the observation may be accounted for if Mimas, like Jupiter, has a number of small bodies moving in tadpole orbits about its equilateral lagrangian equilibrium points. These bodies must also be in near-resonance with Tethys, hence their orbits probably have appreciable forced eccentricities.

Origin of rare gases in the Earth

Minoru Ozima

Geophysical Institute, University of Tokyo, Tokyo 113, Japan

Kiyoshi Nakazawa

Department of Physics, Kyoto University, Kyoto 606, Japan

Although terrestrial rare gases have elemental abundances similar to those of meteorites (planetary-type rare gases), their Ne and Xe isotopic compositions are quite different which suggests that degassing of meteoritic materials alone cannot explain the atmospheric rare gases. The terrestrial rare gases must contain heavily fractionated rare gases captured by planetesimals during a fragmentation process (planetesimal-type rare gases) as well as the planetary type rare gases.

THE approximate similarity in elemental abundance pattern between the Earth and meteorites has led many investigators to assume^{1,2} that terrestrial rare gases were derived from those trapped by chondritic materials, that is, the planetary-type rare gases. However, the isotopic compositions of the atmospheric Xe and Ne are significantly different from those in the chondrites³. It is clearly not possible to derive the terrestrial Xe and Ne simply from the chondrite rare gases and the explanation for the difference should be sought in the pre-planet conditions rather than in the particular evolution processes in the Earth or in the chondrites after their formation³. Astrophysical considerations also indicate that the grains condensed from the solar nebula which subsequently formed the Earth had mostly existed around the present Earth orbit⁴, whereas chondrite parent bodies are generally regarded to have formed further from the Sun, most likely near the asteroidal belt (~2–4 AU) (refs 5, 6). Because the physical conditions in the solar nebula such as temperature and pressure must be different between the asteroidal belt and the Earth orbit, there seems no compelling reason to suppose that

the original Earth materials had trapped the rare gases in the same way as did the chondritic meteorites or their parent bodies. For example, the low temperature adsorption hypothesis⁷ which was proposed to explain the chondritic rare gas pattern is not applicable to the Earth, as the nebula temperature around 1 AU was too high, ~225 K (ref. 8) for grains to adsorb any significant amount of rare gases. This consideration does not, however, rule out the possibility that some of the terrestrial rare gases were supplied from the chondrites, as part of the chondritic materials must have been brought to the Earth's region by the gas drag force and mixed with the materials which formed the Earth⁹. In fact, chondritic materials must be called for to explain the material balance, particularly that of the volatile elements in the Earth^{10,11}. The past decade has seen considerable progress in astrophysics, such as the discovery of the fragmentation process^{12–14} and the subsequent formation of planetesimals. We show here that astrophysical theory leads to a conclusion that a substantial amount of gravitationally-fractionated rare gases must have been captured by planetesimal which later formed the Earth. Hence, the terrestrial rare gases consist of both these planetesimal type rare gases and those trapped in the chondritic materials, that is, the planetary type rare gases. This mixing model can explain the large isotopic fractionation of the terrestrial Xe relative to the planetary and solar type Xe. Except for the Kr and Ar ratio, the model is also consistent with other characteristics of the terrestrial rare gases.

Constraints on terrestrial rare gases

The characteristic features of the rare gases in the Earth which any theory should explain are summarised below. (For the detailed compilation of the terrestrial rare gas characteristics outlined here, see ref. 3.)

(1) The rare gases are depleted relative to the solar abundance. The depletion ranges from 10^{-6} (Xe) to 10^{-11} (Ne). The elemental abundance pattern is similar to that of the planetary type rare gases except for Xe, the latter being more depleted in the Earth.

(2) The isotopic composition of terrestrial Xe shows large mass-dependent fractionation relative to the planetary Xe, in that the heavier isotopes are more enriched (about 4% per AMU). The pattern is surprisingly linear with mass number for all but ^{129}Xe and the heaviest isotopes (see Fig. 2). Departure from the linear fractionation at the heavy end is usually attributed to fission effects, and at ^{129}Xe to extinct radioactive ^{129}I .

(3) Ne isotopic abundance is different both from the solar and planetary Ne (Ne B and Ne A respectively), in that the terrestrial

Fig. 1 Rare gas elemental abundance ($\log_{10} D$) relative to the solar abundance in planetesimals of various sizes (R) are plotted against a mass number. The amount of rare gases is normalised to Si. In the case of the atmospheric values (thick line), M_i stands for the rare gases in the atmosphere and Si in the whole Earth. Note that the mixing of the gravitationally fractionated planetesimal type (thin lines) and the planetary type rare gases (dotted line) would approximate the atmospheric pattern. [$D = (M_i/\text{Si})_{\text{atm}} / (M_i/\text{Si})_{\text{solar}}$].

Fig. 2 Isotopic fractionation pattern for Xe in planetesimals of various sizes relative to SUCOR Xe (ref. 3) (SUCOR designates surface-correlated gas in lunar soil, which is regarded to be close to the solar composition). Lines indicate the fractionation for a planetesimal with a radius R (cm), which resulted from the gravitational fractionation in the planetesimal.

Ne lies roughly midway between the two types in a $^{20}\text{Ne}/^{22}\text{Ne}$ - $^{21}\text{Ne}/^{22}\text{Ne}$ diagram.

(4) In spite of the large difference in Ne and Xe isotopic compositions between the Earth and chondrites, Ar, and Kr seem to exhibit nearly the same isotopic compositions, although terrestrial Kr shows slight enrichment in the lighter isotopes of $\sim 0.5\%$ per AMU. However, the constraints (3) and (4) may not be as stringent as the constraints (1) and (2), because of uncertainties in defining the representative planetary Ne and Kr isotopic ratios.

Planetesimal type rare gases

There are numerous astrophysical theories of the origin of the Solar System and the formation of the planets. Here, we follow the astrophysical theories developed by Hayashi and his colleagues^{13,15-17}. According to these authors, grains condensing from the solar nebula gradually sedimented to the median plane. When the sedimented grain density exceeds a critical value ($\sim 10^{-7} \text{ g cm}^{-3}$), the grains would suddenly collapse to form numerous planetesimals, of size about 10^{18} g . This process is called fragmentation of the dusty layer and was obtained from the astrophysical dynamics independently by Safronov¹², Hayashi¹³ and Goldreich and Ward¹⁴. As the fragmentation occurred $\sim 10^4$ - 10^5 yr after the formation of the proto-Sun¹⁶, there still existed solar nebula gas during the fragmentation. The planetesimals thus formed were loosely-compacted grain ensembles, in that the central pressures were ~ 1 - 10^2 atm for planetesimals with radii 10^6 - 10^7 cm respectively¹⁷. Hence, there must have been considerable inter-grain free space or porosity, which was filled with the solar nebula. The time constant for the heavier rare gases to reach gravitational equilibrium within a planetesimal of a radius R (cm) is of the order of $R^2/(4 \times 10^{10}) \text{ yr}$ (R in cm), whereas the growth time for a planetesimal is $\sim 10^4$ yr (ref. 18). Hence, the rare gases in a planetesimal with a radius less than a few hundred kilometres are in gravitational diffusion equilibrium. When a planetesimal grows further, the gases are no longer in equilibrium and are 'frozen' in the last equilibrium state, corresponding to a planetesimal with a radius of a few hundred kilometres. The rare gases thus frozen in the planetesimals were finally incorporated in the terrestrial planets.

For rare gases in gravitational equilibrium within the planetesimals the density distribution can be expressed as

$$\frac{1}{\rho_i} \frac{dP_i(r)}{dr} = -\frac{GM(r)}{r^2} \quad (1)$$

$$M(r) = \frac{4}{3} \pi r^3 \rho_s$$

where ρ_i , ρ_s are the densities of the rare gas i and the planetesimal solids (assumed to be constant), P_i the pressure of the rare

gas i , G the gravitational constant, M the mass of the planetesimal, r the distance from the centre of the planetesimal. Assuming that the rare gases follow the equation of state for an ideal gas and that the temperature is constant, equation (1) yields:

$$\rho_i(r) = \rho_i(R) \exp(A\mu_i(1-x^2))$$

$$A = \frac{H}{kT} \frac{2\pi}{3} \rho_s GR^2$$

$$x = r/R$$

where k is Boltzmann's constant, T the absolute temperature, μ_i the atomic weight of the rare gas i , H the mass of hydrogen atom, R the radius of the planetesimal and $\rho_i(R)$ is assumed to be equal to the density in the surrounding nebula at the surface of the planetesimal ($r = R$). Hence, assuming a constant porosity s for various size of planetesimals, the total mass M_i of the rare gas in the planetesimal is written as,

$$M_i = 4\pi s \int_0^R r^2 \rho_i dr \quad (2)$$

$$= 4\pi R^3 s \rho_i(R) \exp(A\mu_i) \int_0^1 x^2 \exp(-A\mu_i x^2) dx$$

We then define a retention factor iD

$${}^iD = (M_i/M_{\text{Si}})_p / (M_i/M_{\text{Si}})_{\text{solar}}$$

where Si denotes a conventionally chosen standard element Si and the subscript p refers to a planetesimal. Considering that the mass ratio of the solid phase to the gas phase in the condensing solar nebula is 0.00343 (ref. 19), the retention factor iD can be expressed with the aid of equation (2),

$${}^iD = 0.00343 \times s \rho_g / \rho_s$$

$$\times 3 \exp(A\mu_i) \int_0^1 x^2 \exp(-A\mu_i x^2) dx \quad (3)$$

or

$${}^iD = ({}^iD)_0 \alpha_i$$

$$({}^iD)_0 = 0.00343 \times s \rho_g / \rho_s$$

$$\alpha_i = 3 \exp(A\mu_i) \int_0^1 x^2 \exp(-A\mu_i x^2) dx$$

where $({}^iD)_0$ corresponds to the retention factor for the planetesimal with a negligible gravitation ($A \rightarrow 0$), ρ_g nebula gas pressure and α_i indicates the enrichment factor of the rare gas i due to the gravitational force of the planetesimal.

In Table 1, we show the values of α_i for planetesimals of various sizes. To calculate α_i , we took $\rho_s = 2$ (in cgs) and $T = 225 \text{ K}$, the values being estimated for the solar nebula at 1 AU

Table 1 Enrichment factor α_i for rare gas i in planetesimals with various radius R

$R(\times 10^7 \text{ cm})$	α_i				
	^4He	^{20}Ne	^{36}Ar	^{84}Kr	^{130}Xe
0.12	1.00	1.00	1.00	1.00	1.00
1.2	1.00	1.02	1.03	1.08	1.13
6.1	1.10	1.64	2.61	14.3	99.5
7.3	1.18	2.10	4.34	67.3	1.46×10^3
8.6	1.20	2.87	8.48	500	4.1×10^4
12	1.47	12.2	190	2.9×10^6	8.7×10^{10}

(ref. 8). For the smaller planetesimals ($R \leq 10^6 \text{ cm}$) the enrichment is negligible, whereas a planetesimal with $R = 8 \times 10^7 \text{ cm}$, Xe enrichment amounts to more than 10^4 .

Figure 1 displays the relative elemental abundances of the planetesimal type rare gases normalised to the solar abundances, for which we used a value of $\rho_s = 3 \times 10^{-8}$ (in cgs) at 1 AU (ref. 8) and $S = 0.33$ deduced as the ratio of $(\rho - \rho_s)$ to the density of crystalline silicate ($\rho \approx 3$). The horizontal line (dashed line) represents the case $A = 0$ (no gravitational field), for which $\sim 10^{-11}$ depletion occurs in all rare gases, corresponding to the ratio of the solid to the gas phases in the planetesimal. Figure 1 also shows the rare gas abundance patterns in both the terrestrial atmosphere (thick line) and the planetary type rare gases (dotted line) relative to the solar abundance. Although the planetesimal type rare gases can roughly account for the elemental abundance, the pattern is not exactly the same as that observed in the atmosphere. As discussed above, we must also take into account the planetary type rare gases which were introduced by chondritic materials in the terrestrial atmosphere. A mixing of the two types would better approximate the atmospheric rare gas abundance pattern.

Rare gas isotopic fractionations in planetesimals

The gravitational mass fractionation mechanism also leads to an isotopic fractionation. Isotopic fractionation is conveniently expressed in terms of δ -values relative to the solar isotopic composition. In the case of Xe δ_i will be defined conventionally as

$$\delta_i = (i\text{Xe}/^{130}\text{Xe})/(i\text{Xe}/^{130}\text{Xe})_{\text{solar}} - 1$$

δ_i is then expressed in terms of the retention factor iD , and thus of α_i defined in equation (3),

$$\delta_i = (D_i)/(D^{130}\text{Xe}) - 1 = (\alpha_i)/(\alpha^{130}\text{Xe}) - 1 \quad (4)$$

As $\mu_i \gg 1$ and $\mu_i \gg \Delta_i \equiv |\mu_i - 130|$ for the Xe isotopes, equation (4) can be approximately expressed as

$$\delta_i \approx \left\{ A - \frac{3}{2} \frac{1}{130} \left(1 - \frac{1}{\alpha_i} \right) \right\} \Delta_i$$

Hence, the gravitational mass fractionation indicates a linear mass fractionation trend in agreement with the observation. Table 2 shows the isotopic fractionation δ_i per atomic mass unit for various A , that is, for the planetesimals with various radius R . The isotopic mass fractionation is larger for the heavier rare gases and for the larger planetesimals.

Table 2 Isotopic fractionation factor δ_i (see text for the definition) for rare gas i in planetesimals with various radius R

$R(\times 10^7 \text{ cm})$	δ_i			
	^{20}Ne	^{36}Ar	^{84}Kr	^{130}Xe
1.2	$< 10^{-4}$	$< 10^{-3}$	$< 10^{-3}$	$< 10^{-3}$
6.1	$< 10^{-2}$	0.01	0.02	0.03
7.3	0.01	0.02	0.03	0.04
8.6	0.02	0.04	0.06	0.07
12	0.16	0.18	0.20	0.21

For planetesimals larger than $8 \times 10^7 \text{ cm}$, Xe isotopic fractionation amounts to $\sim 7\%$ per AMU. The δ_i values or a mass fractionation line calculated for various size of planetesimals are shown in Fig. 2 together with the case for the atmospheric Xe. Figure 2 shows that the atmospheric Xe mass fractionation trend can be explained as a mixture of fractionated planetesimal type Xe with the planetary type Xe which shows little mass fractionation relative to the solar isotopic ratio. Owing to the small mass number, the planetesimal Ne isotope shows little mass fractionation relative to the solar type Ne. Hence, we expect from the mixing model that the terrestrial Ne has the isotopic composition somewhere between the planetary and the solar type rare gases; this is, in fact observed in the terrestrial Ne (ref. 3). Because of the particular shapes of the retention factor D for the planetesimal and the chondrite (Fig. 1), that is, upward concave for the former and downward concave for the latter, the planetesimal type Ar and Kr could be less conspicuous in a mixture in which planetesimal gas is the major contributor of Ne and Xe. This may account for the approximate similarity in the Ar and Kr between the planetesimal and planetary-type rare gases, while Xe and Ne isotopic compositions are significantly different from each other.

Origin of the rare gases in the Earth

We first adopt the generally accepted assumption that the terrestrial atmosphere is of a secondary origin, in that the atmosphere was degassed from the interior of the Earth²⁰. We also assume that the atmospheric rare gases essentially represent the rare gases in the whole Earth.

We conclude that the terrestrial rare gases can be interpreted as a mixture of planetary type rare gases which were added to the Earth by chondritic materials and the planetesimal type rare gases captured by planetesimals which later accreted the Earth. As we do not know the exact size distribution of the planetesimals which later accreted the Earth, it would be meaningless to attempt a quantitative estimation of the degree of mixing between the two types of the rare gases. Here we would only suggest that mixing of roughly equal amounts of the planetary- and planetesimal-type rare gases can explain some of the observed characteristic of the terrestrial rare gases: (1) the enormous depletion of the rare gases relative to the solar abundance, with the light rare gases more depleted; (2) the large Xe isotopic fractionation ($\sim 4\%$ per AMU) with nearly a linear mass dependence; (3) the difference in Ne isotopic compositions among terrestrial, planetary, and solar type rare gases. The situation here—previously seen as a mixing of the two latter to make the first—has not been affected by our model because the planetesimal modifications of the isotopic composition of neon should be small. On the other hand, difficulties for the model are the isotopic uniformities everywhere for argon and krypton because we would expect the planetesimal effects on argon, and especially krypton, to introduce effects which are not, in fact seen. Also, the model does not offer a direct explanation of the Xe deficiency in the atmosphere relative to the planetary type rare gases. We suggest that the deficiency may be due to the difficulty in its degassing from the Earth.

For the origin of the planetary type rare gases, we offer no specific explanation; it could be low temperature adsorption⁷, or crystal growth trapping²¹ or others²²⁻²⁴, but the specific mechanism for the origin is not important in the present discussion. Finally, the mixture model should also apply to other inner planets. We therefore suggest that Xe and Ne isotopes should show similar isotopic fractionation trends relative to the solar type isotopic compositions to those observed in the terrestrial rare gases.

We thank Professor C. Hayashi for discussions; and Professors F. A. Podosek and J. H. Reynolds for helpful comments.

Synthesis in *E. coli* of a polypeptide with human leukocyte interferon activity

Shigekazu Nagata, Hideharu Taira, Alan Hall, Lorraine Johnsrud, Michel Streuli, Josef Ecsödi, Werner Boll, Kari Cantell* & Charles Weissmann

Institut für Molekularbiologie I, Universität Zürich, 8093 Zürich, Switzerland

* Central Public Health Laboratory, SF 00280 Helsinki, Finland

Double-stranded cDNA prepared from the 12S fraction of poly(A) RNA from interferon (IF)-producing human leukocytes was cloned in Escherichia coli using the pBR322 vector. One of the resulting clones had a 910-base pair insert which could hybridise to IF mRNA and was responsible for the production of a polypeptide with biological IF activity. Up to 10,000 units IF activity per g of cells was obtained from some clones.

CELLS of almost all vertebrates, when exposed to certain viruses or inducers, produce one or more (glyco)proteins, known as interferons^{1,2}. Interferons (IFs) are characterised biologically by their ability to induce in target cells a virus-resistant state which is associated with the *de novo* synthesis of several proteins, in particular a protein kinase³, an oligoisoadenylate synthetase^{4,5} and a phosphodiesterase⁶. In addition, IFs have a regulatory effect on the immune response^{7,8} and their enhancement of

killer lymphocyte activity⁹ may be the basis of their inhibitory effect on tumour growth².

Two major classes of acid-stable (type I) IFs have been recognised in man—leukocyte interferon (Le-IF), released by stimulated leukocytes, and fibroblast interferon (F-IF), produced by stimulated fibroblasts. Le-IF and F-IF differ not only immunologically but also in their target cell specificity: whereas both IFs induce a virus-resistant state in human cells, Le-IF is also very active on bovine, porcine and feline cells, whereas F-IF is not². The two IFs are encoded by separate mRNAs¹⁰.

Human Le-IF has been purified more than 80,000-fold, to a specific activity of 4×10^8 units per mg (ref. 11) or 2.5×10^8 units per mg (ref. 12). Two components have been characterised by polyacrylamide gel electrophoresis, with apparent molecular weights (MWs) of 21–22,000 and 15–18,000, respectively^{13,14}; they are believed to differ in their degree of glycosylation¹⁴. Enzymatic¹⁵ or chemical¹⁶ removal of most or all of the carbohydrate moiety seems to have little effect on the biological activity of IF.

We sought to clone human Le-IF cDNA in order to construct bacterial strains producing polypeptide(s) with human IF activity, and to generate the tools required for the analysis of Le-IF gene structure and function. The particular difficulties of this undertaking were the lack of a purified Le-IF mRNA and our ignorance of the structure of Le-IF, which precluded the preparation of pure or highly enriched IF cDNA, or of a probe for the identification of the desired clones.

We describe here the isolation of a hybrid plasmid containing a 872-base pair Le-IF cDNA, which elicits the formation in *Escherichia coli*, of a polypeptide with the immunological and biological properties of human Le-IF.

Isolation of hybrid plasmids containing IF cDNA sequences

Hybrid DNA, consisting of leukocyte cDNA sequences joined to pBR322 at the *Pst*I site by means of dG:dC sequences, was prepared by conventional means, using as starting material a 12S fraction of poly(A) RNA from IF-producing leukocytes, purified about 10-fold for IF mRNA. cDNA cloned in this fashion is usually flanked by *Pst*I sites and, as it is located in the

Fig. 1 Hybridisation of IF mRNA and ¹²⁵I-globin mRNA to filter-bound DNAs. DNA was linked to DPT paper as described elsewhere³⁶. *a*, For each time point, one 0.25-cm² piece of DPT paper with 500 ng of *Hind*III-excised insert of rabbit β-globin cDNA plasmid and one piece with 700 ng of *Hind*III-digested pBR322 were hybridised as a sandwich with 10 μl of hybridisation medium²² containing 200 ng ¹²⁵I-labelled globin mRNA. *b*, As above except that DPT papers contained 250 ng of *Hind*III-excised insert of rabbit β-globin cDNA plasmid and 250 ng of *Pst*I-excised insert of Hif-2h, respectively, and hybridisation was with 5 μg of Le poly(A) RNA in 10 μl. In all cases hybridisation, washing and elution were as described in ref. 22. The RNA was recovered, its ¹²⁵I radioactivity determined, and injected into 40–50 oocytes. In experiment *b*, oocytes were incubated with 50 μCi ³H-histidine. Oocyte supernatants were assayed for IF activity by the cytopathic effect reduction assay (see Table 3 legend). Le poly(A) RNA (1 μg) injected directly into 20 oocytes gave 2,700 units IF. For the determination of ³H-labelled globin formation, oocytes were homogenised, centrifuged and an aliquot of the supernatant electrophoresed through a 20% polyacrylamide gel³⁷. The globin band was cut out and the radioactivity determined in toluene-based scintillator solution. 100 ng globin mRNA injected directly gave 100,000 c.p.m. ³H-globin. *a*, ¹²⁵I-RNA hybridised to β-globin cDNA (○) or to pBR322 (●). ³H-labelled β-globin formed in oocytes after injection of RNA hybridised to β-globin cDNA or (Δ) pBR322 (▲). *b*, IF activity formed in oocytes after injection of RNA hybridised to Hif-2h fragment (○) or β-globin cDNA (●).

Hybrid DNA containing leukocyte cDNA was prepared as follows. To obtain poly(A) RNA from IF-producing leukocytes, 10^{11} human leukocytes were primed with Le-IF and induced with Sendai virus as described elsewhere²¹. After 5 h at 37°C the cells were collected, suspended in 1 l PBS and added to 17 l 20 mM Tris-HCl (pH 7.5), 1 mM EDTA and 2% SDS. The lysate was digested with Pronase (200 μ g ml⁻¹) for 1 h at 20°C. 2 M Tris-HCl buffer (pH 9, 5% vol) was added and the solution extracted with 15 l phenol for 30 min. Chloroform (3 l) was added to aid phase separation, the aqueous phase adjusted to 0.3 M NaOAc buffer (pH 5.5) and the nucleic acid precipitated with ethanol. The precipitate (about 1 g) was dissolved in 900 ml TNE [Tris-HCl (pH 7.5), 100 mM NaCl, 5 mM EDTA] containing 0.5% SDS, extracted three times with phenol and exhaustively with ether, and the poly(A) RNA recovered by three batch adsorptions to 3 \times 5 g oligo(dT) cellulose (type 7, P-L Biochemicals) followed by elution with water. The yield was 1.6 mg; 1 μ g gave rise to 300 units IF when injected into oocytes. For further purification, 860 μ g RNA in 5 mM EDTA were passed through a Chelex-100 column, heated for 90 s at 100°C and centrifuged through a 5–23% sucrose gradient in 50 mM Tris-HCl (pH 7.5), 1 mM EDTA and 0.2 M NaCl. The fractions containing the IF-mRNA activity, sedimenting around 12S, were pooled and the poly(A) RNA recovered by oligo(dT) cellulose chromatography. The yield was 40 μ g; 1 μ g gave rise to 3,600 units IF when injected into oocytes. pBR322-linked Le-cDNA was prepared essentially as described previously²². Sucrose-gradient purified poly(A) RNA from two preparations (48 μ g) was used as template for reverse transcriptase to generate 10 μ g cDNA 600–1,000 nucleotides long; this was converted into double-stranded DNA by DNA polymerase I, and treated with S₁ endonuclease (yield, 8 μ g preparation A). Of this DNA, 5 μ g were centrifuged through a sucrose-density gradient, and material sedimenting faster than a 600-base pair ³²P-DNA marker was pooled and precipitated with ethanol (preparation B, 3 μ g). cDNA was elongated with dCMP residues, annealed to dGMP-elongated, PstI-cleaved pBR322 (ref. 17) and used to transform *E. coli* χ 1776 (ref. 23) (preparation A; 3.3×10^4 tetracycline-resistant transformants per μ g DNA), or *E. coli* HB101 (preparation B; 4×10^4 transformants per μ g DNA). Ten thousand colonies of transformed *E. coli* χ 1776 were inoculated individually into wells of microtitre plates and stored with 20% glycerol at –20°C. Five thousand colonies of transformed *E. coli* HB101 (from preparation A) were raised on Millipore filters and stored frozen as described by Hanahan and Meselson^{22,24}. To carry out the hybridisation translation assay, the number of bacterial clones (from preparation A) indicated in the table were inoculated individually on to agar plates, incubated for 24 h and washed off with medium. This suspension was used to inoculate 1–1 cultures from which plasmid DNA was purified as described (method B in ref. 25). The hybrid Le cDNA (20 μ g) was cleaved with HindIII, mixed with 12 μ g Le poly(A) RNA, 5 ng ¹²⁵I-labelled rabbit β -globin mRNA (5,000 c.p.m.) and 0.1 μ g PstI-cleaved rabbit globin cDNA plasmid (Z-pBR322(H3)/Rc β G-4.13)²⁶ in 40 μ l 80% formamide, 0.4 M NaCl, 10 mM PIPES buffer (pH 6.4) and 5 mM EDTA, and heated for 4 h at 56°C. After diluting to 1 ml with 0.9 M NaCl and 0.09 M trisodium citrate (pH 7) and adjusting to 4% formamide, the solution was filtered through a Millipore filter (13 mm diameter, 0.4 μ m pore size). The filter was washed for 10 min at 37°C in 0.15 M NaCl, 0.015 M trisodium citrate and 0.5% SDS, and the RNA recovered by heating the filter for 5 min in 0.5 ml 1 mM EDTA, 0.5% SDS and 3 μ g ml⁻¹ yeast RNA at 75°C. The RNA was purified by oligo(dT) cellulose chromatography, precipitated with ethanol and assayed for IF-mRNA activity. To determine IF-mRNA activity, the RNA sample (up to 3 μ g) was dissolved in 1–3 μ l 15 mM Tris-HCl (pH 7.5) and 88 mM NaCl, and injected into 20–60 *Xenopus laevis* oocytes²⁷ (50 nl per oocyte). Oocytes were incubated for 12–16 h in Barth's medium²⁸, homogenised in 0.5 ml 50 mM Tris-glycine buffer (pH 8.9) and the supernatant was assayed for IF. In later experiments (Table 2), incubation was for 24–48 h and the incubation medium was assayed for excreted IF²⁹. IF was determined by the vesicular stomatitis virus (VSV) plaque reduction assay²¹. All values are expressed in international units. Values marked with an asterisk were obtained by hybridisation to diazobenzoyloxymethyl (DBM)-bound DNA, as described in ref. 22. Underlined values are considered positive. The control values (in parentheses) were obtained by hybridisation to pBR322 DNA. All manipulations involving live *E. coli* HB101 or *E. coli* χ 1776 containing Le cDNA-pBR322 hybrids were carried out in P3 containment conditions as described in the NIH Recombinant DNA Research Guidelines.

β -lactamase gene, can be expressed as a fused protein¹⁷ or, in certain circumstances, as an independent polypeptide¹⁸.

We identified an IF cDNA clone by a mRNA hybridisation translation assay¹⁹. Hybrid plasmid was prepared from pools of 512 bacterial clones, and 20 μ g of each plasmid pool were cleaved with PstI, denatured and annealed with 12 μ g crude Le poly(A) RNA. ¹²⁵I-labelled globin mRNA and rabbit β -globin cDNA plasmid were added to monitor hybridisation and all subsequent steps. Hybridised RNA was recovered from the filters, purified and injected into oocytes to determine its IF-mRNA activity. Control hybridisations were carried out with pBR322. The overall recovery of β -globin mRNA activity was only about 5% of the input.

Four out of 12 groups of 512 clones (δ , λ , I and N) gave positive results by this assay, albeit erratically; controls were consistently negative in these groups (Table 1). However, in later experiments, controls occasionally gave a positive result, perhaps due to insufficient washing of the filters. A group of clones was scored as being positive if the value was higher than in the parallel control. The bacterial clones of group λ were arranged in 8 subgroups of 64 each, and assayed as above. Three of these subgroups, λ -II, λ -III and λ -IV, gave positive responses; the clones of λ -III were regrouped into eight sets of eight.

The set λ -III-4 was the first to yield a positive result; λ -III-2 subsequently also gave positive results. DNA was prepared from the single λ -III-4 clones and that from λ -III-4C gave positive responses both by liquid and filter-bound hybridisation (Table 1). After recloning in *E. coli* HB101 the hybrid plasmid of clone λ -III-4C, designated Z-pBR322(Pst)/HcIF-4c (abbreviated to Hif-4c), was purified and cleaved with PstI; it released a 320-base pair insert, that is, a fragment about one-third of the expected length of complete IF cDNA. The fragment bound IF mRNA efficiently (Table 2).

A set of colonies containing hybrid DNAs related to Hif-4c was identified by *in situ* hybridisation with ³²P-labelled Hif-4c PstI fragment. Among the 64 clones of λ -III, three gave a strong hybridisation response, namely 4C, 2H and 7D, and two (1E and 3D) a weak one. λ -III-2H had the largest insert, about 900 base pairs; it was recloned in *E. coli* HB101 and designated Z-pBR322(Pst)/HcIF-2h (abbreviated to Hif-2h). In addition, 5,000 clones prepared as described, but using double-stranded Le-IF cDNA selected for length above 600 base pairs (preparation B, cloned in *E. coli* HB101), were screened by *in situ* hybridisation, using the same probe. Of 185 positive clones identified, 95 gave a strong and 90 a weak hybridisation response in the Grunstein-Hogness assay²⁰. The former were

designated *E. coli* HB101(Z-pBR322(*Pst*)/HcIF-SN1 to -SN95) (abbreviated to SN1 to SN95).

Properties of plasmid Hif-2h

The insert of plasmid Hif-2h, released by *Pst*I cleavage, was attached to diazophenylthioether (DPT) paper and the kinetics of hybridisation to IF mRNA in conditions of DNA excess determined (Fig. 1). In optimal conditions, about 7% of the IF-mRNA activity and 12% of the β -globin-mRNA activity were recovered, as measured in the oocyte system. Thus, the insert of Hif-2h hybridises to IF mRNA with about the same efficiency as does β -globin cDNA to β -globin mRNA.

Restriction and sequence analysis of Hif-2h (M. Schwarzstein, N. Mantei and M.S., unpublished results) showed that the insert has 910 base pairs of which 23 are 5'-terminal and 15 are 3'-terminal GC pairs; there is one site each for *Bsp*I (85), *Bgl*II (335) and *Eco*RI (710) endonucleases, two sites for *Pvu*II (125, 425), and three sites for *Ava*II (190, 385, 655) and none for *Hha*I, *Taq*I, *Hind*III, *Hpa*II, *Pst*I and *Bam*HI. (The values in parentheses indicate the distance in base pairs from the *Pst* terminus corresponding to the 5' end of the mRNA.) The orientation of the cDNA insert, as ascertained by nucleotide sequence analysis, was such that the reading direction of the IF cDNA coincided with that of the β -lactamase gene.

Detection of IF activity in *E. coli* strains transformed with Hif-4c-related hybrid plasmids

The isolated Hif-2h *Pst*I fragment was joined to *Pst*I-cleaved pBR322 and to three plasmids, pKT279, pKT280 and pKT287, derived from pBR322 by deletions in the β -lactamase gene; DNA ligated into the *Pst* site of this set can be translated in the three possible reading frames by readthrough from the β -lactamase sequence (K. Talmadge, personal communication). *E. coli* HB101 strains transformed with these hybrid DNAs were *E. coli* HB101 (Z-pBR322(*Pst*)/HcIF-2h-AH1 to -AH4), *E. coli* HB101 (Z-pKT279(*Pst*)/HcIF-2h-AH1 to -AH8) and so forth, or in abbreviated form, 322-AH1 to -AH4, 279-AH1 to -AH8, and so on. S-30 or S-100 extracts, from 24 of the AH and 49 of the SN strains grown to stationary phase, were tested for IF activity. The original Hif-2h-containing strain and many of the AH strains showed IF activity; three of them, 279-AH8, 280-AH3 and 287-AH6, were selected for further testing. Of

Table 2 Characterisation of the insert of hybrid plasmid Hif-4c by the mRNA hybridisation translation assay

DNA fragment	Amount of leukocyte poly (A) RNA (μ g)	Time of hybridisation (h)	IF activity (units ml ⁻¹)
Hif-4c	2.5	16	250; 100
β -globin cDNA	2.5	16	4; 1
Hif-4c	7.5	16	3,000; 1,000
β -globin cDNA	7.5	16	4; 30
Hif-4c	7.5	5	1,000; 1,000
β -globin cDNA	7.5	5	10; 1

The insert of plasmid Hif-4c was excised with *Pst*I, purified by electrophoresis through a 2% agarose gel and recovered by successive adsorption to and elution from hydroxyapatite and DEAE cellulose. 120-ng fragments were linked to each 0.25 cm² DPT paper (B. Seed, personal communication). Pre-hybridisation, hybridisation and elution of RNA were as described elsewhere²². The RNA was injected into oocytes and IF activity was determined after 48 h by the cytopathic effect reduction assay³⁰ (see Table 3 legend).

the 49 SN strains, 16 had IF activity; two of the highest producers, SN35 and SN42, and a negative control, SN32, were further examined. Table 3 shows the results obtained with S-100 extracts of log phase bacteria. IF activities ranged from 100 to 1,000 units per ml of S-100 extract derived from a 20-ml resuspension of the 2.0 g (approximately) of bacterial cells contained in 1 l of culture.

Characterisation of the IF activity produced in transformed *E. coli*

We tested the sensitivity of the IF activity to a protease by incubating S-100 extracts of 287-AH6 and SN35 for 30 min at 37°C with increasing amounts of trypsin. As a control, authentic human Le-IF was mixed with the (inactive) S-100 extract of SN32 (to give a similar protein concentration, 6 mg ml⁻¹) and digested in parallel. In all cases, the activity was partially abolished at 200 μ g ml⁻¹ and completely abolished at 1 mg ml⁻¹ trypsin.

Table 3 IF activity in extracts of transformed *E. coli*

S-100 extracts of <i>E. coli</i> HB101 transformed by:	IF activity (units per ml extract)
a Z-pBR322(<i>Pst</i>)/HcIF-2h	100; 100
b Z-pKT279(<i>Pst</i>)/HcIF-2h-AH8	100; 300
c Z-pKT280(<i>Pst</i>)/HcIF-2h-AH3	1,000; 1,000
d Z-pKT287(<i>Pst</i>)/HcIF-2h-AH6	200; 200
e Z-pBR322(<i>Pst</i>)/HcIF-SN35	1,000; 1,000
f Z-pBR322(<i>Pst</i>)/HcIF-SN42	300; 100
g Z-pBR322(<i>Pst</i>)/HcIF-SN32	0; 0

The IF-cDNA insert of Hif-4c, excised with *Pst*I and purified as described in Table 2 legend, was joined to *Pst*I-cleaved pKT279, pKT280 and pKT287, respectively. *E. coli* HB101 was transformed with these products and tetracycline-resistant colonies were screened by *in situ* hybridisation²⁰ as described by Hanahan and Meselson²⁴, using the Hif-4c *Pst*I fragment nick-translated with [α -³²P]dATP (1,100 Ci mmol⁻¹, NEN) and [α -³²P]dCTP (470 Ci mmol⁻¹, NEN) as labelled substrates³¹. Three clones (b-d) were selected in preliminary assays for IF activity. Clones c-g were from a set of IF-cDNA-containing clones identified among 5,000 *E. coli* HB101 transformed with Le cDNA (preparation B, see Table 1 legend) by *in situ* hybridisation as above. e and f were shown to produce IF in a preliminary screening, and g was chosen as negative control. One-litre cultures of transformed *E. coli* were grown to an A₆₅₀ of about 0.8. The cells (about 2.0 g) were collected, washed with 50 mM Tris-HCl (pH 8), 30 mM NaCl and resuspended in 20 ml of the same buffer. Lysozyme was added to 1 mg ml⁻¹; after 30 min at 0°C, the suspension was frozen and thawed five times and centrifuged at 10,000 r.p.m. for 20 min. The supernatant was centrifuged at 40,000 r.p.m. for 1 h in a Spinco 60 rotor. The S-100 supernatants (about 6 mg ml⁻¹ protein in all cases) were assayed in duplicate by the cytopathic effect reduction assay and their IF content estimated relative to a standard IF preparation. IF activity was determined by the cytopathic effect reduction assay as follows. The IF samples, serially diluted 1:3 were mixed with 10⁵ CCL23 cells in the wells of a microtitre plate (Cooke) in MEM-10% newborn calf serum. After 24 h the medium was replaced by an appropriate dilution of Mengo virus in the same medium. 24 h later the medium was replaced with 0.5% crystal violet, 3% formaldehyde, 30% ethanol and 0.17% NaCl for 15 min; the wells were then washed exhaustively with water.

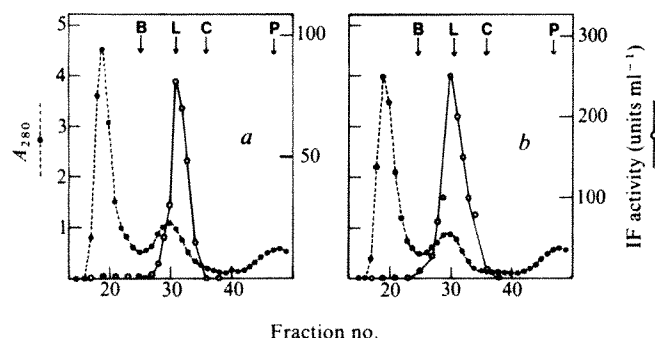

Fig. 2 Chromatography of Le-IF and *E. coli* IF on Sephadex G-100. (a) 0.9 ml S-100 extract of 280-AH3 (500 units, 6 mg protein ml⁻¹) and (b) 0.9 ml of a dilution of human Le-IF (1,000 units of preparation P-IF (ref. 34)) in S-100 extract of SN32 (no IF activity, 6 mg ml⁻¹) were mixed with cytochrome c (0.2 mg) (C), ³²P-phosphate (10⁵ c.p.m.) (P) and ¹²⁵I-labelled β -lactoglobulin (2.5 \times 10⁵ c.p.m.) (L) and chromatographed on a 0.9 \times 49-cm column of Sephadex G-100 in PBS at 4°C. Fractions of 0.7 ml were collected at 2.3 ml h⁻¹. IF activity was measured by the cytopathic effect reduction assay, and radioactivity, A₂₈₀ and A₄₁₀ (cytochrome c) were determined for each fraction. The position of bovine serum albumin (B) was determined in a separate run, relative to C and P.

Table 4 Antibody titres of anti-Le-IF and anti-F-IF measured against different IF preparations

	Le-IF	F-IF	S-100 <i>E. coli</i> extracts	
			SN35	280-AH3
Sheep anti-Le-IF	100,000	3,000	30,000	30,000
Goat anti-F-IF	<10	1,000	<10	<10

About 10 units of each IF preparation were incubated for 1 h at 20°C with different antiserum dilutions and the IF activity was determined by the VSV plaque reduction assay³². The titres are given as the reciprocal of the highest dilution which raises the plaque counts by a factor of 2. The sheep anti-Le-IF was prepared as described elsewhere³³. Human Le-IF was purified to the P-IF stage³⁴.

Human Le-IF is stable at pH 2 (ref. 21). S-100 extracts of 280-AH3 and SN35, as well as 250 units human Le-IF mixed with (inactive) S-100 extract of SN32, were dialysed overnight against 0.1 M NaCl and 50 mM glycine-HCl (pH 2) buffer and then 5 h against phosphate-buffered saline (PBS). A precipitate was removed by centrifugation and the supernatant assayed by both cytopathic effect reduction and plaque reduction. In all cases the initial IF activity was recovered in full.

To compare the MWs of authentic Le-IF and the IF activity in transformed *E. coli* (*E. coli* IF), S-100 extracts were chromatographed on Sephadex G-100 columns. IF activity moved with a K_{av} of 0.46 in the case of 280-AH3 (Fig. 2a), 281-AH6 and SN35 (data not shown), which was slightly slower than authentic Le-IF (mixed with S-100 extract of SN32, Fig. 2b); the difference may, however, not be significant.

We compared the serological properties of authentic IFs and *E. coli* IFs. As shown in Table 4, sheep anti-human Le-IF had a similar titre against Le-IF and *E. coli* IF of SN35 and 280-AH3, and was $\frac{1}{30}$ th as active on fibroblast IF (F-IF); goat anti-human F-IF was active only against F-IF. Thus, *E. coli* IF is immunologically similar to Le-IF, and quite distinct from F-IF.

Both authentic Le-IF and *E. coli* IFs show specificity in regard to the cells on which they will act: they are most active on human cells, less active on monkey and mouse cells and inactive on chick cells (Table 5). It is not clear whether the relatively high activity of *E. coli* IF on monkey cells is significant; further experiments with the purified material are necessary.

As shown by Kerr^{4,5} and others, treatment of cells with IF increases 10- to 15-fold their level of oligoadenylate synthetase, an enzyme that condenses ATP to ppp(A2'p)_n5'A ($n = 1-4$). Cells were treated with various IF preparations and the cell extracts assayed by measuring the ³H radioactivity transferred from ³H-ATP to the dephosphorylation products of pppA2'p5'A and ppp(A2'p)₂5'A, namely (2'-5')ApA and (2'-5')ApApA. As shown in Table 6, (2'-5')ApA radioactivity was six- to ninefold higher in cells treated with Le-IF or *E. coli* IF than in controls treated with an inactive *E. coli* extract, and (2'-5')ApApA radioactivity was more than 14-33 times higher than in controls; there was no significant difference between the activity of Le-IF and S-100 extracts of 280-AH3 and SN35.

Table 5 IF activities measured on different cell types

Cells Expt 1	Le-IF	Interferon activity		
		F-IF	<i>E. coli</i> S-100 extracts	
			280-AH3	SN35
Human U amnion	6,000	2,000	600	600
Monkey Vero	600	600	350	350
Monkey GMK	350	200	350	110
Primary chick embryo fibroblasts	<20	<20	<20	<20
Cells Expt 2	Le-IF	mouse-IF	<i>E. coli</i> S-100 extracts	
			287-AH6	SN35
Human CCL23	1,000	ND	300	1,000
Mouse L929	40	120	40	120

Human Le-IF was preparation P-IF (ref. 34), mouse IF was the NIH standard. U cells were maintained by K.C. All cells were challenged with VSV, except for CCL23 cells, where Mengo virus was used. Experiment 1 was assayed by plaque reduction, experiment 2 by the cytopathic effect reduction assay. ND, Not done.

Thus, by all criteria tested, *E. coli* IF is very similar to authentic Le-IF, although, of course, the molecular structure may well differ in various respects.

Discussion

A strain of *E. coli* containing IF-cDNA was identified by an IF-mRNA hybridisation translation assay in which DNA from successively smaller pools of strains was screened. Because only 4 of 12 groups of 512 clones had originally given a positive response, we were surprised to find 5 IF clones in a selected group of 64. It is probable that, when used on large pools, the assay was at borderline sensitivity and only detected groups and subgroups particularly rich in IF-cDNA clones. The subsequent screening of 5,000 colonies using an IF-cDNA probe revealed 185 positive clones, a frequency of about 1:27. Taking into account the fact that the poly(A) RNA used to generate the clones had been enriched about 10-fold with respect to IF mRNA, the proportion of IF mRNA in poly(A) RNA from induced leukocytes was not less than 1:270.

The identification of the 910-base pair insert in Hif-2h as a cDNA copy of human Le-IF rests on two lines of evidence: (1) its capacity to hybridise selectively to IF mRNA, and (2) its ability to direct the synthesis, in *E. coli*, of a polypeptide with the

Table 6 Levels of oligoadenylate synthetase in human cells treated with Le-IF or *E. coli* IF

Cells treated with:	Cell protein (μg)	³ H-A in oligoadenylate (% of recovered radioactivity)	
		ApA	ApApA
1. S-100 extract of SN35 (200 units IF ml ⁻¹)	7.6	1.4	<0.1
	38	5.2	1.4
2. S-100 extract of 280-AH3 (200 units IF ml ⁻¹)	7.6	1.5	0.1
	38	7.8	3.3
3. S-100 extract of SN32 (no IF)	7.6	<0.1	<0.1
	38	0.9	<0.1
4. Le-IF (P-IF) (200 units IF ml ⁻¹)	7.6	1.3	0.25
	38	8.0	2.1

Confluent CCL23 cell monolayers in 50-mm dishes were treated with a mixture of 1 ml *E. coli* S-100 extract and 4 ml minimal essential medium (MEM)-10% newborn calf serum or a dilution of Le-IF (P-IF) in 5 ml medium. After 20 h the cells were lysed and supernatants prepared as described elsewhere³⁵. Varying amounts of lysate were adsorbed to poly(rI).(rC)-Sephacrose and incubated as described elsewhere³⁵, except that ³H-ATP (specific activity 40 Ci mmol⁻¹) was used instead of ³²P-ATP. After treatment with bacterial alkaline phosphatase, the products were separated by electrophoresis using ApA and ApApA as markers³⁵. The paper was cut into strips and the radioactivity determined by scintillation counting. Most radioactivity was recovered in adenosine. 100% radioactivity was 3-5 × 10⁴ c.p.m.

biological activity of IF. The polypeptide has properties of human Le-IF in that it induces a virus-resistant state in human cells, to a lesser extent in monkey and mouse cells and not in chick cells, and is neutralised by antibody to human Le-IF but not to human F-IF. Moreover, *E. coli* IF stimulates the activity of isoadenylate synthetase in human cells to the same extent as does authentic Le-IF.

The IF-cDNA plasmids were constructed to allow synthesis of an IF molecule fused to part of β -lactamase. It seems likely, however, that the biologically active material is a non-fused polypeptide, because its formation is directed by hybrids derived from each of the three pKT plasmids and is therefore independent of the reading frame resulting from the construction. Moreover, a fused β -lactamase fragment should contribute 180 amino acids when the IF cDNA is inserted in the *Pst*I site of pBR322, but not more than 26 or 29 amino acids when it is linked to pKT280 or pKT287 (K. Talmadge, personal communication); in fact, there is no detectable difference in the size of the biologically active IF polypeptides made by the three strains. At the structural level, *E. coli* IF probably differs from authentic Le-IF by the absence of appropriate glycosylation. Also, it is possible that *E. coli* IF consists of the Le-IF sequence preceded by a signal sequence, as nucleotide sequence analysis of the cloned IF cDNA revealed a region coding for 22 amino

acids which follows the first AUG and precedes the stretch coding for mature IF (M. Schwarzstein, N. Mantei and M.S., unpublished results).

We do not know whether *E. coli* IF has the same specific activity as authentic Le-IF. If this were the case, the amount of active IF produced in transformed *E. coli*, about 20,000 units per l of culture, would correspond to one to two fully active molecules per cell. This would be consistent with the occurrence of rare translational events at the physiological initiation site of the IF sequence, and appropriate modifications of the hybrid plasmid should allow a considerable increase in the yield of active IF. If, however, lack of appropriate glycosylation diminishes the activity of the molecule, we shall have a problem on our hands.

Lethal metabolism of precocene-I to a reactive epoxide by locust corpora allata

G. E. Pratt, R. C. Jennings, A. F. Hamnett & G. T. Brooks

Agricultural Research Council, Unit of Invertebrate Chemistry and Physiology, University of Sussex, Brighton BN1 9RQ, UK

The corpora allata from adult female Locusta migratoria rapidly metabolise precocene-I to a geometric mixture of dihydrodiols, and simultaneously suffer extensive macromolecular labelling. This could explain the selective cell death which precocenes induce, and focuses attention on the high level of epoxidase in these insect organs.

It is not known how the natural product precocene-I (ref. 1), its congener precocene-II (ref. 1), or related analogues², cause selective necrosis^{3,4} of cells in the corpora allata (CA) of sensitive insects. Therefore, it has not been possible to rationalise the activity or inactivity of precocene analogues², or to explain the marked species specificity of these compounds. An early suggestion⁵ that precocenes might act on the brain, which normally controls the CA, has received no further experimental support. Initial experiments on the isolated CA of a relatively insensitive species were inconclusive⁶. More positive evidence for a direct action of precocenes on the CA comes from studies on CA of adult female *Oncopeltus*⁷, in which 87% of CA failed to elicit a positive response in a transplantation bioassay after culture for 5 days in a medium containing 4.5×10^{-5} M precocene-II. The likelihood of an oxidative biotransformation being crucial to the action of precocene was raised by our recent finding⁸, that its action on both *Oncopeltus* and *Locusta* is suppressed by co-treatment with certain benzodioxole mixed function oxidase inhibitors, although these seem to protect precocene against metabolic inactivation. We speculated⁸ that a crucial activating metabolism of precocenes may occur within the CA, which might explain their tissue specificity. Accordingly, we have synthesised radiolabelled precocene-I, and

studied its metabolism by CA and non-target tissues of adult female *Locusta migratoria*, *in vitro*. Our results strongly indicate that the CA rapidly oxidise precocene-I at the 3,4 double bond to a highly reactive⁹ epoxide, much of which forms covalent attachment to cellular macromolecules. We suggest that this may be the basis of the cytotoxic action of precocenes. By contrast, non-target tissues are not subjected to intense labelling of macromolecules, which may be important in determining the selective action of precocenes. Our hypothesis focuses attention on the enzymic competence of the CA to oxidise precocene-like molecules to highly reactive epoxides.

Precocene metabolism and covalent attachment to macromolecules

We synthesised [4-³H]precocene-I (2,2-dimethyl-7-methoxychromene) at 34 mCi mmol¹⁰. Authentic reference compounds I–IV (Fig. 1) were prepared for identification of possible metabolites by published methods^{1,9,11}, all being known compounds. 2,2-Dimethyl-7-hydroxy-chromene¹² was prepared by the method of Bowers *et al.*¹ from the corresponding chromanone¹¹. The dihydrodiols (IV)¹³ were prepared from the *m*-chloroperoxybenzoic acid adducts to precocene-I (ref. 9) after separation of *cis* and *trans* forms (Waters Prep system 500,

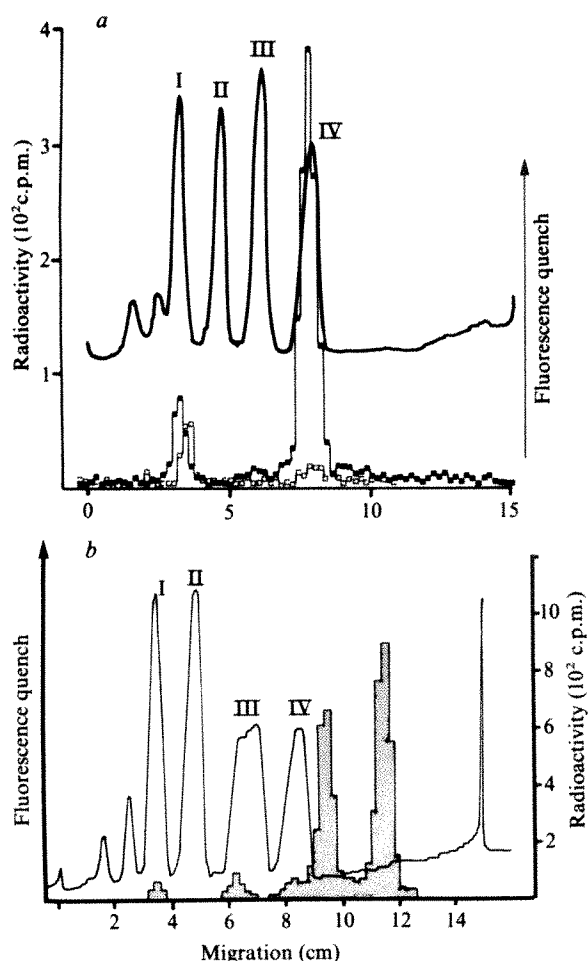

Fig. 1 Radio-TLC analysis of precocene-I metabolites produced by several locust tissues *in vitro*. *a*, Five lots of two pairs of CA from 14-day-old adult female *Locusta migratoria*, reared as described elsewhere⁸, were incubated by shaking in the dark at 30 °C in 0.1 ml each of TC 199 medium (2 mg ml⁻¹ FicollTM, 20 mM HEPES buffer, pH 7.2 at 30 °C) with [4-³H]precocene-I (34 mCi mmol⁻¹; 99.3% radiochemical purity by quantitative RP-TLC) at an initial concentration of 0.101 mM, for 3 h. Incubation tubes and glass transfer pipettes were coated with 5% aqueous Carbowax 20 M. The incubation was stopped by exhaustive extraction on the centrifuge with ethyl acetate (containing 20–50 µg nonradioactive reference compounds) the extract dried with anhydrous sodium sulphate, and the volume reduced under nitrogen flow before TLC application. RP-TLC was carried out on Merck 0.25 mm KC-18 indicator plates, pre-washed in alumina purified ethyl acetate then AR methanol, after application to 1.5 × 1.5-cm area. The samples were prefocused twice with redistilled methanol then developed, in a darkened sandwich chamber for 15 cm in methanol:water (7:3). Authentic internal reference compounds were localised by fluorescence quenching densitometry (continuous line) (Vitatron TLD), and radioactivity localised by windowless gas flow counting (Berthold scanner, 1-mm window, scaler mode, background 3 c.p.m.). Reference compounds: I, 2,2-dimethyl-7-methoxy-chromene (precocene-I); II, 2,2-dimethyl-7-methoxy-chroman-4-one; III, 2,2-dimethyl-7-hydroxy-chromene and 2,2-dimethyl-7-methoxy-chroman-4-ol (poorly resolved); IV, *cis, trans* 3,4-dihydroxy-2,2-dimethyl-7-methoxy-chroman (precocene-I dihydrodiols). ■, CA incubation; □, control incubation without tissue. *b*, Similar experiment to *a*, using Malpighian tubules, except that the initial precocene concentration was 0.14 mM, and the combined incubations were blended in 5 ml of redistilled ethyl acetate before repeated extraction. Qualitatively similar results were obtained with ligatured mid-guts and abdominal fat body sheet.

two series mounted silica PrepPAKs 5.7 × 30 cm, 30% diethyl ether in pentane) by base hydrolysis (1M NaOH, 50% aqueous ethanol) 30 min at room temperature). All compounds were characterised by appropriate physical methods. When CA from reproductively mature female *Locusta* were incubated in tissue culture medium containing labelled precocene-I for 1–5 h, and the incubations partitioned between either salt solution/chloroform + methanol, or /ethyl acetate, negligible radioactivity (<1.5%) was found in the aqueous phase. Analysis of the chloroform layer by reversed-phase thin layer chromatography (RP-TLC) suggested that there was only one important metabolite (96% of products) in the CA, which co-chromato-

graphed with a mixture of *cis/trans* 3,4 dihydrodiols, whereas the selected non-target tissues (abdominal fat body, ligatured mid-gut and Malpighian tubules) produced varying quantities of material of intermediate polarity (Fig. 1). In two experiments, half the chloroform layer was also analysed by normal phase TLC (silica gel; ethyl acetate: xylene, 25:75) with mutually consistent results (data not shown). When the CA were separated from the incubation medium at the end of the experiment by gland transfer¹⁴, and extracted separately, more than 99% of the dihydrodiol present was found to be in the surrounding medium. Analysis of the extracted CA revealed up to 400 pmol precocene equivalents per gland pair bound to non-extractable residues, whereas the radioactivity associated with non-extractable residues from the non-target tissues was much less (~4–15 pmol per animal equivalent) after 3 h incubation. In three experiments, duplicate CA samples were subjected to further extraction with 10% TCA before solubilisation and radioactivity determination, with only slight (1–8%) loss of radioactivity. We take this to be evidence of covalent attachment, but have yet to demonstrate either its nature or cellular location. Depending on the initial concentration of precocene in these experiments (range 1.7×10^{-5} – 4.4×10^{-4} M) CA macromolecules were labelled to the extent of 7.8–80 nmol per mg tissue protein. These are very high values. For example, the lowest value is 80 times the degree of labelling of rat liver protein *in vivo* following administration of an hepatotoxic dose of bromobenzene, even when protection by endogenous glutathione is at its minimum¹⁵.

We studied the time course of precocene–dihydrodiol formation and macromolecule labelling in the CA by replacing the substrate medium every 30 min (Fig. 2a), thereby maintaining the precocene concentration within a defined range. Figure 2a shows a trend towards progressively increased rate of dihydrodiol release over a period of 2.5 h. Macromolecules are labelled at a constant rate in these conditions, after an extrapolated lag period of 9 min. We also examined the time course of metabolism during incubations in which an initially high precocene concentration was allowed to decline exponentially for 3 h. Figure 2b shows one such experiment, resulting in a final concentration of 7×10^{-5} M, and it is clear that dihydrodiol formation and macromolecule labelling proceed unabated over this period. Other experiments showed that the metabolic rate varies with, but is not proportional to, the precocene concentration over the range studied.

Stereochemistry of precocene dihydrodiols

To identify the dihydrodiols further, we isolated 2.9×10^5 d.p.m. by RP-TLC, and analysed aliquots by high resolution silica HPLC (Fig. 3). Of the radioactivity recovered (94% of that applied), 96% co-chromatographed exactly with authentic internal markers of *cis* and *trans* dihydrodiols, with radioactivity in the ratio *trans*:*cis*, 62:38. We also examined the very much smaller quantities of dihydrodiol produced by the three other tissues studied, where it does not accumulate progressively, and obtained *trans*:*cis* ratios of 63:37 to 80:20.

We believe that the high *cis* content of the dihydrodiol produced by the CA is important evidence of trigonal hybridisation in a reaction intermediate, namely the 3-OH, 4-carbocation which would result from proton catalysed opening of the 3,4 epoxide ring; it is known that chemical hydration of precocene-I 3,4-epoxide yields significant quantities (21–36%) of *cis* dihydrodiol in a wide variety of conditions (ref. 9 and A. F. H., A. P. Ottridge, G. E. P., R. C. J. and K. M. Stott, unpublished results). This proposed hydration mechanism, and the high reactivity of precocene-I epoxide⁹, compares readily with that deduced for the reactive epoxides of benzo(α)pyrene 7,8-dihydrodiol¹⁶ and many other mammalian carcinogens¹⁷. This contrasts markedly with the relatively stable epoxide group in the natural product (juvenile hormone) of the CA, whose acid-catalysed hydration is predominantly S_N2 in character and leads to 97% *trans* dihydrodiol¹⁸. Enzymic hydrolysis of epoxides typically yields *trans* dihydrodiols¹⁹. Apparently, dihydrodiols

Fig. 2 Progressive formation of dihydrodiols and labelled macromolecules from [4-³H]precocene-I by *Locusta* CA, *in vitro*. Glands were incubated as in Fig. 1, but at different precocene-I concentrations. Δ , Incubations were extracted with 25 volumes of CHCl₃:methanol (10:1) and the extracts analysed by RP-TLC for precocene-I dihydrodiol content. \blacksquare , Labelled macromolecules were estimated after removal of the CA from the aqueous phase on stainless steel loops and extraction twice in 0.5 ml methanol (6 h), before solubilisation (0.2 ml Lumasolve, LKB, 2 h, 45 °C with shaking) and liquid scintillation counting (4.7 ml Lumagel, LKB, neutralised with glacial acetic acid, shaken for 1 h) in a Wallac 81000 calibrated on AES ratio with standard tritiated water (Amersham), in minivials. Radioactivity on RP-TLC plates was qualitatively localised by gas-flow β -imaging (Panax Betagraph) and correlated with the fluorescence quenching profile of authentic *cis/trans* precocene-I dihydrodiols, which were recovered by scraping into micro-filter tubes under suction, and quantitatively eluted with 8 \times 0.2 ml methanol into 9.5 ml of toluene-based scintillator²⁵ for scintillation counting. *a*, CA were bilaterally randomised between five incubation tubes (four glands per 0.1 ml culture medium) and incubated for different total periods, in duplicate, in 2.3×10^{-5} M [4-³H]precocene-I. The medium was recovered by aspiration every 30 min, for analysis by RP-TLC, and replaced with fresh medium, until the end of the experiment. The degree of cumulative labelling of cellular macromolecules was determined at the end of each incubation; each point represents the mean of two separate observations, and the straight line is a fitted linear regression ($r = 0.96$). The stock solution of substrate in TC 199 was stable at 0 °C. \circ , The concentration of precocene-I at the end of each 30-min interval was determined by subtracting the radioactivity found in the dihydrodiol zone after RP-TLC, from the total radioactivity in the medium (determined by scintillation counting of a 5- μ l aliquot of a 1:1 mixture and ice-cold methanol prepared immediately after aspiration of the medium from the CA). The points are variously the means of 2–10 estimations, and standard errors are indicated where appropriate. The saw-tooth line joining the concentration points is purely illustrative (compare with *b*). The final balance of radioactivity was completed by elution of the plastic incubation caps in toluene (10% ethanol) scintillant. *b*, Similar to *a*, except that the incubations were initiated at 4.45×10^{-4} M [4-³H]precocene-I, and the media were not replaced during the course of the incubations. Each point is the mean of two determinations.

are important metabolites of precocene-II in whole insects of several species²⁰, and in an isolated non-target tissue (fat body) from two insensitive species²¹, but their stereochemistry has not been reported. We have used standard methods²² to investigate epoxide hydrolase activity in isolated *Locusta* CA with [12-³H]C₁₆ juvenile hormone (340 mCi mmol⁻¹) as substrate, and

Fig. 3 High resolution liquid chromatograph of precocene-I dihydrodiols produced by *Locusta* CA *in vitro*, and isolated by RP-TLC. Radioactivity in the dihydrodiol zone after RP-TLC (Fig. 1a) was eluted with a total of 1.5 ml redistilled dichloromethane, filtered and evaporated. The sample was dissolved in HPLC solvent, and 4.8 μ l (6,914 d.p.m.) analysed on 5 μ m Zorbax-sil (250 \times 4.6 mm; diethyl ether:pentane:2-propanol (49.9:49.9:0.2), 1.5 ml min⁻¹). Fractions of effluent were collected every 12 s for determination of radioactivity.

failed to find any (detection limit ~ 1 pmol h⁻¹ per gland pair), which is in accord with the physiological function of these glands. Thus, if dihydrodiol formation in the CA is a consequence of epoxidation, the final hydration step is almost certainly a spontaneous chemical event, proceeding via a reactive carbocation which would be expected to alkylate cellular nucleophiles^{9,15} in competition with its reaction with water. Apparently, our proposed pathway may account for both the stereochemistry of the dihydrodiols and the labelling of cellular macromolecules.

Sensitivity to a mixed function oxidase inhibitor

We sought evidence for an initial lethal synthesis involving epoxidase action on precocene-I by studying the effect of a mixed function oxidase (MFO) inhibitor on precocene metabolism in the CA. Many MFO inhibitors are known to inhibit juvenile hormone (JH) biosynthesis in both whole cockroach CA²³ and homogenates thereof²⁴. As part of a larger study

Fig. 4 Inhibition of precocene-I and farnesenic acid metabolism in *Locusta* CA by EMPB, *in vitro*. CA were bilaterally randomised between control and experimental tubes, and pre-incubated with the appropriate concentration of EMPB for 30 min before addition of radiolabelled substrates²³. When precocene-I was the substrate it was present at an initial concentration of 0.12 mM, and radiolabelled incubation was for 2 h. Precocene-I (\bullet) dihydrodiols and labelled macromolecules (\circ) were determined as described in Fig. 2 legend. When farnesenic acid was the substrate the media contained [12-³H]2E,6E-farnesenic acid (309 mCi mmol⁻¹; 2.6×10^{-5} M), and [Me-¹⁴C]methionine (Amersham; final activity 35.4 mCi mmol⁻¹; 1.6×10^{-4} M). Methyl farnesate and juvenile hormone (∇) were quantified by extraction, silica gel TLC and liquid scintillation counting²⁵. Inhibition values were the same whether calculated on ³H or ¹⁴C radioactivity. The data are composed from two separate experiments, each point representing a single observation except those at 10⁻⁴ M EMPB, which are duplicates.

(G.T.B., G.E.P. & J. A. Cocks, unpublished) we synthesised ethyl (2*E*)-4-(3,4-methylenedioxyphenoxy) butanoate (EMPB) by transesterification (BF₃/ethanol) of the corresponding methyl ester derived from the esterification of sesamol with methyl 4-bromo-2*E*-butanoate (K₂CO₃/dimethoxyethane, 60 °C). The compound was 98% pure by HPLC (5 µm Zorbax-sil, *N*_{eff} = 9,300, pentane: diethyl ether: s-propanol 9.9: 89.9: 0.2). We tested this compound in a standard assay for inhibition of spontaneous C₁₆H biosynthesis in cockroach CA²³, and found an IC₅₀ of 8 × 10⁻⁶ M coupled with a large accumulation of methyl farnesoate, unlike some other MFO inhibitors which seemed to inhibit both epoxidation and esterification reactions in the biosynthetic pathway²³. EMPB also inhibits C₁₆H biosynthesis from exogenous farnesenic acid²⁵ in *Locusta* CA (Fig. 4), although it seems to be slightly less active in this system. More importantly, Fig. 4 shows that adult female *Locusta* CA are almost equally sensitive to EMPB in respect of: (1) epoxidation of internally generated methyl farnesoate; (2) precocene-I dihydrodiol formation; and (3) precocene labelling of macromolecules. We observed no significant diversion of precocene-I metabolism towards other products in the presence of EMPB. These results demonstrate that an oxidative enzyme is crucial to both ultimate pathways of precocene metabolism in the CA. Kinetic studies on a partially purified methyl farnesoate epoxidase from adult female *Locusta* CA have revealed high

levels of activity, with typical *v*_{max} values of 1–2 nmol min⁻¹ per mg total tissue protein (R. Feyereisen & G. E. P., unpublished results). We have yet to demonstrate that precocene-I is a lethal alternative substrate for this enzyme, but suspect this to be the case, because the specialised endocrine function of the glands makes it unlikely that they will be rich in other oxidases involved in general detoxifying metabolism.

Conclusions

The oxidative activation of precocene-I in *Locusta* CA may be compared with the various types of oxidation which are believed to be crucial to the action of aromatic cytotoxins¹⁵, neurogenic neurotransmitter analogues²⁶ and carcinogenic polycyclic aromatic hydrocarbons^{16,17} in vertebrate tissues. In these cases, the mechanisms of possible importance include the generation of epoxides^{15–17}, quinonoids^{26,27} and reactive forms of oxygen^{26,28}. Causative interpretation of these findings has been particularly difficult in the case of polycyclic aromatic hydrocarbons because of the multiplicity of metabolic pathways²⁹. In contrast, the present studies suggest that precocenes are metabolised by a single enzymic pathway in the CA; which should facilitate investigation of their selective cytotoxic action.

We thank P. Minkin and staff for insects, F. A. Mellon and P. E. Meadows for physical data, B. A. J. Alexander and B. M. B. Caseley for technical assistance.

Emission at 3.3 µm and evidence for dust in 3C273

David A. Allen

Anglo-Australian Observatory, PO Box 296, Epping,
New South Wales 2121, Australia

The presence of dust grains in a variety of astronomical environments has been established from many IR observations¹. Of particular interest is whether dust exists in the highly energetic quasars, and in the less energetic (but apparently similar) Seyfert 1 galaxies. Whilst both quasars and Seyfert 1 galaxies exhibit enhanced radiation over just the wavebands expected of thermal dust emission, the interpretation of this enhancement is a matter of controversy². The origin of the non-thermal radiation that quasars emit at other wavebands is not understood; hence a non-thermal origin of their enhanced IR continua cannot be excluded. The existence of dust also has relevance to current discussions on the hydrogen emission-line ratios, for the weakness of the broad Lyα emission can possibly be explained by absorption on dust grains^{3,4}. I present here circumstantial evidence that dust exists in the quasar 3C273, by demonstrating the existence of the 3.3 µm line in emission.

Emission at 3.3 µm has been found in many galactic and extragalactic objects. In the most complete reviews of this feature^{5,6}, the wavelength was given as 3.28 µm, and a qualitative correlation with the presence of dust grains was noted. A gas-phase origin of the emission was shown to be unlikely because of the intrinsic width of the feature⁵. Recently an identification with C–H bonds (for example, methane) on the surface of dust grains has been proposed⁷.

Spectroscopic observations were made of the quasar 3C273 using the IR photometer-spectrometer on the 3.9 m Anglo-Australian Telescope. In its spectroscopic mode this instrument makes use of a circular variable filter and is a single-channel fast-scanning spectrometer. A total of 1,800 scans through the spectrum were made in a period of 2.5 hours; the spectral region covered was 3.68–3.96 µm. The spectral resolution was 0.08 µm, and samples were taken every 0.02 µm. For the redshift of 3C273 the expected wavelength of the 3.28 µm feature is 3.80 µm.

The data are presented in Fig. 1. An unresolved emission feature is clearly seen rising about 40% above the continuum and having an equivalent width of 170 ± 40 Å. The rest wavelength of this feature is 3.26 µm. This differs from the observed wavelength of the feature in other objects by 0.3 of the spectral resolution, an amount roughly equal to the uncertainty of the wavelength calibration in this spectral region.

The presence of the 3.28-µm feature is strong circumstantial evidence for the existence of dust somewhere in the immediate

Fig. 1 Spectrum of 3C273 in the rest wavelength range 3.2–3.4 μm . The two broken lines indicate the 1- σ bounds to the estimated continuum based on independent broad-band IR measurements made on the same night (9 April 1979).

vicinity of 3C273. This in turn makes more credible the association of the IR enhancement with thermal radiation from dust. Whether that dust lies within the emitting gas, and therefore can absorb a significant fraction of the Ly α emission, cannot be determined from present data. If, however, the 1–10 μm continuum⁸ in 3C273 is interpreted as thermal radiation from

that dust, the black-body colour temperatures implied range from a few hundred to about 1,000 K. Such temperatures would be found at distances of the order of 10 to 100 pc from the central energy source for a luminosity of about $10^{13} L_{\odot}$ (ref. 8). The dust therefore lies outside at least part of the nuclear region wherein the broad emission lines probably originate. In a study of the effects of dust on the emission-line spectra of quasars, Ferland and Netzer⁹ concluded that the weakness of Ly α could possibly be explained better by dust outside the emission region than within it. However, such statements are inevitably provisional as there is no guarantee that the dust is distributed with spherical symmetry about a quasar's nucleus.

It would be of interest, although difficult, to search for the emission features at 7.8 and 8.7 μm , which are present in most galactic sources having 3.3- μm emission⁶, and which are redshifted to 9.0 and 10.1 μm , both convenient parts of the atmospheric window.

A probable 1970 hard X-ray outburst by 4U0041+32

J. G. Laros

Los Alamos Scientific Laboratory, University of California,
Los Alamos, New Mexico 87545

Wm A. Wheaton

NASA Jet Propulsion Laboratory, 4800 Oak Grove Drive,
Pasadena, California 91103

During a balloon test flight on 4 February 1970, an engineering model of the UCSD Cosmic X-ray Experiment, later flown on the OSO 7 satellite, observed what was apparently an unknown high-latitude X-ray source at $\alpha = 0^{\text{h}} 45^{\text{m}} \pm 5^{\text{m}}$, $\delta = 33^{\circ} \pm 3^{\circ}$. The source had a 25–300 keV flux of about 6×10^{-2} photons $\text{cm}^{-2} \text{s}^{-1}$, and a very hard spectrum over that energy range. By the time of a subsequent balloon flight on 25 September 1970, the intensity had faded to below 10^{-2} photons $\text{cm}^{-2} \text{s}^{-1}$ (99% confidence). Recent observations by several experimenters have led us to associate the balloon observation with the highly variable source 4U0041+32. Certain characteristics of this source, such as its high galactic latitude and hard spectrum extending to ~ 300 keV, set it apart from other known transients.

At the time of the 1970 balloon flights there was no known source in the region. The 2U Catalogue¹ of 1972 contained an entry, 2U0043+32, compatible with the balloon position, but the source was weak (7.8 ± 0.6 Uhuru counts) and not described as variable. Variability was first suggested by MIT OSO 7 data², and confirmed by Murray and Ulmer³ in 1976, based on further analyses of Uhuru data. In 1977 February an X-ray outburst⁴ occurred, during which the source reached an intensity of ~ 50

Uhuru counts. SAS 3 observations⁵ over the following several months improved the source position to a 1 arc min radius error circle, allowing a tentative optical identification by Charles *et al.*⁶. The identification was based on weak He II $\lambda 4686$ emission seen on one of several nights' spectrophotometric observations of the $V \sim 19.2$ mag G-type candidate star. The faintness of the candidate (and the absence of bright stars nearby) seems to require a distance of at least 5 kpc, placing the high latitude object within the galactic halo. Evidence for a possible 11.6-day periodicity has been reported by Watson and Ricketts⁷ from Ariel 5 data, while the SAS 3 observations⁵ limit short-period pulsations to $< 7\%$ of the total flux. The aforementioned discoveries, together with others establishing the hard X-ray transients as fairly common phenomena^{8–12}, have now made it clear

Fig. 1 20–50 keV counting rate versus time during the February 1970 balloon flight. The solid line shows the expected collimator response to a point X-ray source at $\alpha = 0^{\text{h}} 45^{\text{m}}$, $\delta = +33^{\circ}$. The high rates early in the flight are due primarily to Cygnus X–1. Gaps in the data indicate times when the instrument was being calibrated or when the blocking crystal was in the detector aperture.

that the 1970 balloon observation was probably of a prediscovery outburst of 4U0041+32.

The observation was made by a scintillation telescope¹³ consisting of a 64 cm² area, 1-cm thick NaI(Tl) central detector collimated to a $\sim 7^\circ$ FWHM field-of-view by a surrounding CsI(Na) shield in active anticoincidence. As the flight was primarily for test purposes, the instrument was mounted vertically beneath a rotating table that contained an opening, a calibration source, and a NaI blocking crystal. To obtain the maximum amount of diagnostic information, individual central detector events in the 15–550 keV range were pulse-height analysed in a 256-channel linear PHA and telemetered to the ground along with associated shield coincidence tags. The actual anticoincidence vetoing was carried out during subsequent computer analysis. In addition, nearly all central detector and shield discriminator rates and many other housekeeping functions were continuously monitored. Background spectra and calibrations were taken hourly utilising the rotating table, except during the early part of the flight when the Cygnus region crossed the detector aperture.

Fig. 2 Spectral Information on 4U0041+32. The range of intensities seen in the ~ 2 –10 keV range is shown together with the two 1970 balloon observations.

Figure 1 shows 20–50 keV counting rates observed during the flight. The low rates reflect post-flight processing to include the effects of the anticoincidence shielding. A source transit apparently occurred shortly after 22.00 UT. Although the data were never published (due, among other reasons, to the second flight's failure to confirm the source), the apparent transit has all the characteristics expected for a real cosmic X-ray source. First, the hard spectrum of the excess counts (Fig. 2) rules out several alternative possibilities, such as an increase in detector (PMT) noise, an X-ray aurora, or most precipitating particle events. Second, there was no significant increase or decrease in any of the instrument discriminator counting rates during the transit. Possibilities such as a change in anticoincidence efficiency due to degraded shield performance, or any increase in the overall radiation environment, are, therefore, largely excluded. Furthermore, the radiation causing the excess counting rate must have formed a well-collimated beam, because the shield rates, which are sensitive to diffuse or isotropic radiation but relatively insensitive to unidirectional radiation beams, were also constant within the statistical uncertainties. As it is highly

implausible that charged particles could form such a beam and maintain it stably over the ~ 30 min duration and ~ 50 km spatial extent (the balloon drift rate was ~ 100 km h⁻¹) of the observation, the radiation beam must have been a beam of photons—an X-ray source. Finally, the time history of the excess counting rate (Fig. 1) agrees well with that expected from the collimator response to a point source at $\alpha = 0^{\text{h}} 45^{\text{m}} \pm 5^{\text{m}}$, $\delta = 33^\circ \pm 3^\circ$. If we use the scatter in the eight background data points between 20.00–21.30 UT and 22.30–23.00 UT to determine the errors (thereby obtaining errors about 30% larger than those expected from Poisson statistics), the 20–50 keV source transit shown in Fig. 1 has a significance of $\sim 10\sigma$.

Given the moderate sensitivity of our balloon experiment, it seems unlikely that we have obtained the only observation of a high latitude ($b \sim -30^\circ$) variable or transient X-ray source located within 3° of the known variable 4U0041+32. Unfortunately, our incomplete knowledge of the occurrence of this type of object, does not allow us to place a reliable quantitative value on the probability of such a coincidence. Note also that the weak (3 Uhuru counts s⁻¹) source 4U0041+36 could conceivably have been responsible for the 1970 outburst. Nonetheless, as it seems most likely that the balloon source and 4U0041+32 are the same, we shall base the following discussion on that assumption.

The spectrum that we obtained for 4U0041+32 is shown in Fig. 2, along with the 1970 September upper limit and with data from the 1–10 keV observations. While simple power law extrapolations of the high energy data seem generally consistent with those taken at lower energy, the absence of simultaneous measurements over the entire 1–300 keV range prevents us from determining whether spectral changes accompany the intensity variations. In any case, the fact that the spectrum extends to 300 keV, apparently without a break, sets 4U0041+32 apart both from the other hard transients and also from the hard compact binary X-ray sources, which generally have a spectral cut-off below a few tens of keV. The spectrum is similar to, but harder than, spectra of some compact extragalactic sources (for example, Cen A, NGC4151, and 3C273; see refs 14–16) and most resembles the spectra of certain cosmic γ -ray bursts (for example, 14 May 1972; see ref. 17). The source is distinguished from the other hard transients not only by its lack of a high energy spectral cut-off, but also by its position (>2.5 kpc below the galactic plane), by its apparent lack of pulsation⁵, and by not being associated with an early type giant or supergiant companion. Assuming a distance of 5 kpc, the peak X-ray luminosity of $\sim 3 \times 10^{37}$ erg s⁻¹ is in the range observed for other hard transients, and for the hard compact binary X-ray sources.

We thank Roderick Jerde and other members of the UCSD X-ray astronomy group headed by L. E. Peterson. Personnel of the NCAR balloon base in Palestine, Texas, capably handled the launch, tracking, and recovery of the balloon payload. Can pregalactic black holes produce the hard X-ray background?

B. J. Carr*

Department of Astronomy, University of California at Berkeley, California 94720

The possibility that pregalactic black hole accretion could have heated the Universe sufficiently to produce the hard X-ray background through bremsstrahlung emission is considered here. This would only be possible if the holes were implausibly large. However, the radiation produced directly from the accretion could explain both the density and spectrum of the X-ray background providing that the holes had a density of the order of 10^{-6} times the critical density and a mass of the order of $10^9 M_\odot$. We suggest that these holes could be the precursors of the holes which may presently be powering Seyfert galaxies or quasars.

It has been claimed¹ that the spectrum of the extragalactic diffuse X-ray background from 3 to 50 keV is well described as optically thin bremsstrahlung radiation with a temperature of ~ 45 keV. The energy density of this background, $\Omega_x \sim 10^{-8}$ in units of the critical density, could conceivably be generated by known discrete sources² (such as quasars). However, it would be surprising if the superposition of many discrete sources, each presumably having a different spectrum, could produce the very specific background spectrum required, and this suggests³ that the X-ray background may be produced by a uniform intergalactic medium with density $\Omega_g \sim 0.5$ and temperature 5×10^8 K. This would naturally explain why the background should have an optically thin bremsstrahlung spectrum. If such a medium does exist, however, it is hard to explain how it became so hot. Models which invoke quasar heating face severe energetic problems and, although these problems are alleviated if one assumes that the medium is clumped into large clouds, one would then expect anisotropies in the X-ray background larger than is observed⁴.

We first consider whether the intergalactic medium could have been heated to 5×10^8 K as a result of pregalactic black hole accretion. This suggestion is prompted by the realisation that black holes would have been accreting very rapidly at pregalactic epochs and that, if they produced radiation with an appreciable efficiency, they would have inevitably boosted the matter temperature well above the usual Friedmann value, generally causing reionisation. There are many contexts in which a population of black holes could have formed before galaxy formation. They could have been produced even before decoupling if the early Universe had large density fluctuations⁵ or a soft equation of state⁶ or it was highly anisotropic⁷ or cold⁸ or tepid⁹. More conventionally, one might expect holes to form after decoupling when the Jeans mass drops to $10^6 M_\odot$ and regions that size should bind very easily; such regions might either collapse directly or fragment into massive (10^2 – $10^4 M_\odot$) stars which could themselves collapse after their brief nuclear-burning phase of 10^6 yr. Within all these contexts one would expect the holes to have a mass above $10 M_\odot$ and their density Ω_B could, in principle, be close to 1. In this case, they would be good candidates for providing the 'missing' mass in clusters and galactic haloes¹⁰. If their density was very small, they might be identified with the black holes which are suspected of residing in quasars and active galactic nuclei¹¹.

The effect of pregalactic black-hole accretion on the thermal history of the Universe has been studied in detail elsewhere¹².

Here we outline the argument for determining the maximum temperature attained. We assume that the holes are subsonic at pregalactic epochs and that they accrete at the Bondi¹³ rate $\dot{M} \sim 10^{11} M^2 n T_4^{-3/2} \text{ g s}^{-1}$, where M is in solar masses and n and T_4 are the background particle density in cm^{-3} and temperature in units of 10^4 K. (For simplicity we assume a critical background density; in this case $n \sim 10^{-5} z^3$ for $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$.) If the accretion generates radiation with an efficiency ϵ , then holes larger than $10^3 \epsilon^{-1} M_\odot$ will be accreting at the Eddington limit for some period after decoupling and during this 'Eddington phase' we assume such holes radiate at the Eddington limit $L_{\text{ED}} \sim 10^{38} \text{ Merg s}^{-1}$.

We need to know how much of the radiation goes into heating the Universe and how much goes into the background. Photons emitted at a redshift z will go into Compton heating providing their energy exceeds about $10 z^{-3/2} \text{ MeV}$. Thus if most of the radiation is at an energy $E_{\text{max}} = 10 \eta \text{ keV}$, nearly all of it will go into Compton heating at redshifts exceeding $z_* \sim 10^2 \eta^{-2/3}$; the fraction doing so thereafter is just $f_c \sim (z/z_*)^{3/2}$. Photons with energy $\leq z^{1/2} \text{ keV}$ will go into photoionisation heating. If most of the emergent radiation is at an energy higher than this, the fraction which goes into photoionisation heating will be small; for a flat spectrum this fraction is $f_p \sim \eta^{-1} (z/10^3)^{1/2}$.

For even very small values of the black hole density Ω_B one can show that the photoionisation heating will cause the matter temperature to rise at some time after decoupling and eventually reach a value of $\sim 10^4$ K. At this point the ionisation will increase to a value close to 1 due to collisions. Because of the inverse Compton cooling of the 3 K background,

$$\Lambda_r \equiv -\left(\frac{dT}{dt}\right)_r \approx \frac{\sigma_T \rho_r T}{m_e c} \approx 10^{-19} T z^4 \text{ s}^{-1} \quad (1)$$

(where ρ_r is the 3 K radiation density, σ_T is the Thomson cross-section and m_e is the electron mass), T cannot initially rise above 10^4 K. However, it will do so when the Compton heating of the holes

$$\Lambda_c \equiv \left(\frac{dT}{dt}\right)_c \approx \frac{n_B L_{\text{ED}} f_c}{nk} \approx 10^{-3} \Omega_B \text{ K s}^{-1} \quad \text{for } z > z_* \quad (2)$$

(where n_B is the black hole number density) becomes comparable to Λ_r . This occurs at a redshift $z_c \sim 10^3 \Omega_B^{1/4}$. Thereafter T , determined by the balance of Λ_c and Λ_r , rises as z^4 until the accretion rate falls below the Eddington limit at a redshift which can be shown to be

$$z_{\text{ED}} \approx 10^{3.3} \Omega_B^{1/6} (M\epsilon)^{-1/9} \quad (3)$$

(This exceeds z_* for the values of Ω_B and M which are of interest.) After the Eddington phase, Λ_c is reduced and T rises as $z^{-2/5}$ for $z > z_*$ and falls as $z^{1/5}$ for $z < z_*$. At a redshift of the order of 10 the Compton heating time scale falls below the expansion time scale, so T begins to fall faster. However, at about this time the thermal history may be affected by various postgalactic processes (such as quasar heating³), so that our analysis breaks down.

These considerations imply that the maximum temperature is attained at the redshift z_* when f_c falls below 1 and it is

$$T_{\text{max}} \approx 10^{3.2} (\Omega_B M \epsilon)^{2/5} \eta^{4/15} \text{ K} \quad (4)$$

providing this does not exceed the temperature of the hottest accretion-generated photons $\sim 10^8 \eta \text{ K}$. Our estimate of T_{max} is insensitive to the spectrum of the emitted radiation so long as most of the energy is at the upper end (that is, as long as the spectrum is shallower than E^{-1}). Clearly, T_{max} can only be as high as 10^8 K , say, if the holes are very large indeed. Even with the optimal assumptions ($\Omega_B \sim 1$, $\epsilon \sim 0.1$, $\eta \sim 10^3$) one requires M to exceed $10^{12} M_\odot$ and there are independent limits which preclude holes of this size from being very numerous¹⁰. It is,

* Present address: Institute of Astronomy, Madingley Road, Cambridge CB3 0HA, UK.

therefore, implausible that pregalactic black hole accretion could heat the Universe to the temperature required to explain the hard X-ray background, even though one would expect it to reionise the Universe ($T_{\max} > 10^4$ K).

We now consider whether the fraction of generated radiation which does not go into heating the Universe could explain the 45-keV background. After the redshift z_* , this fraction is essentially unity, whereas before z_* it is only $(z_*/z)^{3/2}$. It is easy to deduce¹² that the largest contribution to the background density derives from the epoch z_* and that the redshifted energy generated by each hole is

$$E(M) \approx (\epsilon \dot{M} c^2 z^{-1} t)_* \approx 10^{46} \Omega_B^{-3/5} M^{7/5} \epsilon^{2/5} \eta^{-11/15} \text{ erg} \quad (7)$$

This corresponds to a present background density

$$\Omega_x \approx n_B E(M) / \rho_{\text{crit}} \approx 10^{-8} (\Omega_B M \epsilon)^{2/5} \eta^{-11/15} \quad (8)$$

The present temperature associated with this radiation, as $z_* \sim 10^2 \eta^{-2/3}$, is $E \sim E_{\max} z_*^{-1} \sim 10^2 \eta^{5/3}$ eV. Although equations (7) and (8) were derived previously¹², the 'energy' parameter η was there assumed to be arbitrary and epoch-independent, whereas, for any particular model of black hole accretion, the value of η may itself be determined by M and \dot{M} . In particular, for some disk accretion models¹⁴, there will be a band in the (\dot{M}, M) plane in which one would expect to produce optically thin bremsstrahlung radiation with a well-defined temperature. From the Bondi accretion formula and equation (4), the accretion rate at the epoch z_* is

$$\dot{M} \approx 10^{13} \Omega_B^{-3/5} M^{7/5} \epsilon^{2/5} \eta_*^{-12/15} \text{ g s}^{-1} \quad (9)$$

and the associated 'disk' temperature¹⁴ is

$$\theta_* \equiv 10^8 \eta_* \approx 10 \left(\frac{M}{M_\odot} \right)^{1/2} \text{ K} \approx 10^{7.5} \Omega_B^{-3/10} (M \epsilon)^{1/5} \eta_*^{-6/5} \text{ K} \quad (10)$$

where η_* specifies the value of η at z_* . One expects an optically thin bremsstrahlung spectrum providing θ_* is in the range 10^7 – 10^9 K.

We will not attempt here to investigate whether material accreted pregalactically would, in fact, form an accretion disk; this involves issues too complicated to discuss in the present context. However, note that the present hypothesis would almost certainly fail if the black holes did not form accretion disks. For example, were the accretion spherically symmetric, radiation could still be generated with an appreciable efficiency due to magneto-hydrodynamic dissipation¹⁵. However, because the dominant radiation mechanism would be synchrotron losses in this situation, one could not expect to produce optically thin bremsstrahlung radiation.

Equations (8) and (10) determine Ω_x and the present background temperature T_x in terms of Ω_B and M :

$$\Omega_x \approx 10^{-8} \Omega_B^{1/2} (M \epsilon)^{1/3}, \quad T_x \approx \theta_* z_*^{-1} \approx 10^6 \Omega_B^{-5/22} (M \epsilon)^{5/33} \text{ K} \quad (11)$$

Thus the temperature and (to a lesser extent) the density of the background are remarkably insensitive to the values of Ω_B and M . Indeed, for most hypotheses of pregalactic black hole formation, one would expect to produce a background of optically thin bremsstrahlung X rays, providing the holes accrete according to the disk mode. On the other hand, because the observed value for T_x is specified so precisely, one can still infer the necessary values of M and Ω_B to within an order of magnitude. The present temperature of the radiation, $T_x \sim 10^2 \eta_*^{5/3}$ eV, is 45 ± 5 keV (as required¹) providing $\eta_* = 40 \pm 3$, that is providing the accretion at z_* produces radiation with

energy $E_{\max} \approx 0.4$ MeV. In this case $z_* \sim 10$ and, because $\Omega_x \sim 10^{-8}$, equation (11) implies

$$\Omega_B \sim 10^{-6}, \quad M \epsilon \sim 10^8 \quad (12)$$

Values for Ω_B and $M \epsilon$ much different from these would fail to produce either the density or the temperature of the X-ray background. The largest reasonable value for ϵ is about 0.1; in this case one needs $M \sim 10^9$. Note that the radiation produced at pregalactic epochs before and after z_* will also contribute to the X-ray background at energies around kT_x . However, these contributions will be dominated by the radiation produced at z_* itself if the holes are then producing optically thin bremsstrahlung radiation.

In the above discussion we have assumed that the black holes have a unique mass, whereas one might expect them to span a range of masses. However, equation (11) shows that the dominant effect on Ω_x and T_x comes from the value of M which maximises the products $\Omega_B M^{2/3}$ and $\Omega_B^{-1} M^{2/3}$, respectively. For the anticipated¹⁰ types of mass spectra, the largest holes would have the biggest effect on both Ω_x and T_x , although they may not dominate the total black hole density. The largest holes would also determine the value of T_{\max} . With the favoured parameters ($\Omega_B \sim 10^{-6}$, $\epsilon M \sim 10^8$, $\eta_* \sim 40$), equation (4) implies that the pregalactic medium would have attained a maximum temperature $T_{\max} \sim 10^5$ K at a redshift of ~ 10 . The temperature of the intergalactic medium today would be somewhat different from this (depending on which postgalactic heating sources operate) and its density would depend on how much gas was left over after galaxy formation. It is interesting that recent estimates¹⁶ of the density and temperature of the intergalactic medium inferred from observations of Ly α absorption lines in quasars indicate that T was indeed about 10^5 K at $z \sim 2$.

Note that one cannot expect this picture to produce an exactly 45-keV bremsstrahlung spectrum, partly because the radiation comes from a range of redshifts and perhaps a range of black hole masses, but also because even an individual hole will not have a unique temperature. There will be a superposition of spectra from different points on the accretion disk. All one can state is that the dominant contribution may fit a 45-keV spectrum; a more detailed analysis would be needed to determine whether the distortion due to the lesser contributions would be within the error bars of the data. The important point is that the background conditions should be very uniform before galaxy formation, so one would not expect the range of spectra exhibited in postgalactic sources like quasars. Note that Barrow and Silk have also suggested that pregalactic black hole accretion could generate the X-ray background¹⁹. However, they do not attempt to fit the actual spectrum; nor do they allow for the effect of the accretion on the thermal history of the Universe.

Finally, we consider the radiation produced by the black holes during the present epoch. The production by holes which reside in galactic haloes or clusters has been estimated previously¹². Such holes might in principle generate the density of the background radiation, for suitable values of Ω_B and M , but one would not expect them to accrete at a rate sufficient to produce a 45-keV optically thin bremsstrahlung spectrum. For example, if one assumes reasonable values for n and T ($n \sim 10^{-3}$, $T \sim 10^6$ in haloes; $n \sim 10^{-3}$, $T \sim 10^8$ in clusters), then equation (10) requires $M \sim 10^9 M_\odot$ for halo holes and $M \sim 10^{14} M_\odot$ for cluster holes. Both these possibilities are precluded by observation¹⁰. Liang has considered the possibility that the holes are intergalactic¹⁷ and that the ambient conditions are there as inferred by Sargent *et al.*¹⁶. He argues that such holes could also produce the 45-keV background density. On the other hand, with the sort of values for Ω_B and M required, it is perhaps more plausible to envisage the holes—rather than inhabiting any of the environments discussed above—presently residing in galactic nuclei. For a large black hole would naturally act as a condensation nucleus for a galaxy¹⁸ and the sorts of holes which have been hypothesised to power quasars and Seyfert galaxies¹¹

would indeed have values for Ω_B and M of the order of those we have inferred. In this case one could identify the sources of the hard X-ray background as the precursors of the most prominent X-ray sources at the present epoch. This would please proponents of the view that known sources can produce the background if one allows for evolutionary effects.

Possible transfer of lunar matter to Earth due to a nearby supernova

M. Ruderman & J. W. Truran

Madingley Road, Institute of Astronomy, Cambridge CB3 0HA, UK

Theories of supernova explosion (SNEs)¹⁻³ as well as correlation of NO_3^- in Antarctic ice cores with the dates of historical supernovae⁴, suggest that many Type I SNE may yield an intense 10^{50} erg emission of γ rays. Such a SNE may be expected to occur within a few tens of light years of our Solar System once every hundred million years or so^{5,6}. A short γ -ray pulse of this magnitude would not only directly affect the terrestrial atmosphere in ways that can be important for surface life⁵, but also be absorbed by the lunar surface. Depending on the γ -ray energies involved, the upper centimetre of lunar surface soil can be evaporated by heating or ejected by the emergence at the surface of a rising pressure pulse. Such expelled lunar soil, moving at speeds near the $2 \times 10^5 \text{ cm s}^{-1}$ lunar escape velocity, could be captured by the Earth's gravitational field and gradually settle through the atmosphere to the Earth's surface. Geological strata for that epoch might then be expected to show an overabundance of iridium (but probably less than that found by Alvarez *et al.*⁷ in 65-Myr-old sedimentary layers at Gubbio). This would occur since the expelled lunar surface soil should be characterised by an Ir abundance greatly enriched, relative to terrestrial of lunar rocks, by micrometeorite bombardment.

SNE models often involve a configuration in which the dense exploding stellar core is surrounded by a rather minimal atmosphere^{3,5}. Under such circumstances, the outgoing supernova shock wave propagating through a very steep density gradient will become extremely relativistic. The hot relativistically expanding matter at the shock front emits a burst of radiation when only one optical depth of matter remains to be penetrated. The interval over which this radiation pulse arrives is greatly compressed, due to the relativistic expansion of the radiating matter. Colgate originally estimated a γ -ray flash (with a total energy $\sim 10^{48}$ erg) compressed into a pulse of duration $\leq 10^{-5}$ s (refs 1, 5). There exists a great variation in estimated γ -ray energies, from \sim few MeV upward, and in total energies of the pulse up to $\sim 10^{50}$ erg (refs 2, 3).

A recent analysis of NO_3^- concentrations in an Antarctic ice core revealed the presence of four spikes coincident with historically known supernova⁴. Two of these are known to have been Type I supernovae; the other two are not identified. To explain the large magnitudes of the four NO_3^- spikes, it seemed that at least 10^{50} ergs of X rays or γ rays would have to be emitted by each SNE. This radiation could, however, have arrived over an interval as long as a year rather than as a flash.

No γ -ray flashes have yet been detected in coincidence with extragalactic SNEs. However, the γ -ray flash, which should arrive well before the SN is visually observed, may well be associated only with a specific subclass of Type I SNEs. Furthermore, if the characteristic energies of the γ -rays are very high, it is possible these bursts would have escaped detection: fairly massive detectors need to be flown in satellites to allow the full e^+ shower to develop. We note also that γ rays above $\sim 10^{15}$ eV will produce e^+ pairs in collisions with the universal 3 K black-body radiation photons. This limits the detectability of such γ -ray sources to those within about 10^4 light yr. γ -ray flashes from the historical galactic supernovae could then have reached us, but not those from explosions in other galaxies.

We shall next consider some consequences of an assumed 10^{50} erg γ -ray flash from a SNE at a distance of 30 light yr or less from our Solar System. This would give an incident γ -ray flux in excess of $\sim 10^{10} \text{ erg cm}^{-2}$ locally.

The Earth's atmosphere shields its surface from the direct impact of an intense X-ray or γ -ray pulse. Effects on the surface would be indirect, such as those resulting from NO production and subsequent O_3 destruction. In contrast, the lunar surface receives the full flux. The detailed consequences of this exposure depend somewhat on the regime of incident γ -ray energies.

MeV γ rays, for which Compton scattering is the main energy deposition mechanism, are absorbed by $\sim 1 \text{ g cm}^{-2}$ of lunar surface matter. Thus, $\sim 10^{10} \text{ erg g}^{-1}$ of rapidly absorbed energy will be deposited in the solid surface layer, which has a density of $\sim 1 \text{ g cm}^{-3}$, down to a depth of 1 cm. This will increase the temperature of the centimetre layer to 10^3 – 10^4 K and generally vaporise it, assuming the γ -ray energy is deposited in less than a second (for $T \sim 3 \times 10^3$ K). The kinetic energy required for escape from an isolated moon is also $\sim 10^{10} \text{ erg g}^{-1}$, roughly comparable to the energy provided by the absorbed γ -ray flash. (Because of the Earth's gravitational pull, an additional 40% is needed to escape the Earth-Moon system.) Therefore, the hot evaporated vapour, which temporarily provides the Moon with an atmosphere of density $\sim 10^{-12} \text{ g cm}^{-3}$, will expand to fill and ultimately overflow the Roche lobe. A substantial fraction of this material, flowing through the inner lagrangian point into the Earth's Roche lobe, should ultimately reach the Earth. It would initially form a ring, at a radius of the order of 10^{10} cm , in which the particles have roughly keplerian velocities. Because of the extremely low gas density, $\sim 10^{15} \text{ g cm}^{-3}$, the mean free path for molecular collisions is about 10^{10} cm , that is comparable to the ring dimension. This causes the gas to behave as an extremely viscous fluid. The keplerian differential rotation then causes the main part of the disk to contract on a rapid time scale, if the outer material can be dispersed. During the descent of this lunar matter to the Earth, it would be affected by the solar wind; however, the wind pressure $\sim 10^{-10} \text{ dyn cm}^{-2}$ on 10^{18} g of falling vapour is insufficient to sweep even fully ionised matter of this kind away from the Earth is less than 10 yr (M. Rees, personal communication). Neutral gas will survive for much longer. The accreted lunar gas may take several decades to move (mainly by advection) down through the upper atmosphere and stratosphere and ultimately reach the Earth's surface.

A somewhat different theory for an ejection of lunar surface matter would be required if the SNE γ -ray flash were characterised by photon energies $\gg 100 \text{ MeV}$, arriving within an interval of the order of 10^{-5} s. For these conditions, the incident γ -ray energy is deposited at a depth of a few tens of cm, mainly by ionisation resulting from an electron-position shower which develops over several radiation lengths (l). If the duration of the γ -ray pulse is $\leq 10^{-4}$ s (l over the local sound speed), the energy

is deposited on a time scale less than that for thermal expansion in response to the initial differential heating. The resulting initial pressure excess, the product of the temperature rise, the coefficient of thermal expansion, and the volume compression modulus, is of the order of $10^{10} \text{ l}^{-1} \sim 10^9 \text{ dyn cm}^{-2}$ within the main energy deposition layer. Emergence of this pressure impulse at the lunar surface which has weak or negligible tensile strength should result in mass ejection. Matter ejected at the speed of sound in lunar matter has about the 10^5 cm s^{-1} speed needed to escape from the Moon and still be captured by the Earth.

If a SNE γ -ray flash and the consequent transfer of lunar material to the Earth occurred >60 Myr ago, it would be difficult to find evidence of it on the surfaces of lunar rocks today. Micrometeorite bombardment erodes those surfaces at the rate of $10^{-1} \text{ cm Myr}^{-1}$ (ref. 8), so that direct evidence for or against melting and recrystallisation or fragmentation of the outer centimetre or so of lunar surface matter is unlikely (G. Turner, personal communication). (Some evidence for such a flash might still be found in the form of glassy fragments, which were buried before they could be eroded.) The lunar samples studied have also come from a relatively small region, about 10^3 km across, which would have one chance in two of having been on the dark side of the flash.

If a strong $10^{10} \text{ erg cm}^{-2}$ γ -ray flash is likely every 10^8 years from SNEs uniformly distributed in space and time, a flash of strength $10^{10} \text{ erg cm}^{-2}$ would be expected to have occurred as recently as 10^8 yr ago. Thus, about 10^6 years ago there might have been a final γ -flash of intensity $5 \times 10^8 \text{ erg cm}^{-2}$. This would not have been intense enough to evaporate lunar surface matter but could have melted almost 1 g cm^{-2} of it; that is, to a depth of a few millimetres if the flash γ rays had energies in the X-ray to MeV region. Erosion would not yet have removed all of the melted-recrystallised surfaces. One is tempted to speculate that such a flash might still be in fact observable in the form of the glassy patches emphasised by Gold⁹, who proposed a sudden (solar) flash for the original melting. On the other hand, a relatively nearby SNE may be 'common' only when the Solar System is within a spiral arm, for example, of the order of 60 Myr ago. A SNE γ -ray flash giving $5 \times 10^8 \text{ erg cm}^{-2}$ some 10^6 years ago would then be less likely.

A possible consequence of the transfer of $\sim 1 \text{ g cm}^{-2}$ of the lunar surface to that of the Earth rapidly enough to be, in effect, instantaneous over geologically measurable intervals, is element abundance anomalies at appropriate places in the terrestrial sedimentary layers. Alvarez *et al.*⁷ report a large enhancement in the abundance of Ir, from $0.25 \times 10^9 \text{ g per g}$ of limestone to $6.35 \times 10^{-9} \text{ g per g}$ in a 1-cm layer at Gubbio. This anomaly is identified as occurring at the Cretaceous-Tertiary boundary about 65 Myr ago. The isotope abundance ratio remained normal.

The Earth's surface is deficient in Ir relative to the meteorites by a factor of more than 10^3 . While lunar rocks are also characterised by a large deficiency, the upper centimetre of lunar soil, which is strongly adulterated by micro-meteorite bombardment, can be expected to show significant Ir concentrations. Analyses of Apollo 11 and Apollo 12 lunar soil samples^{10,11} reveal Ir abundances up to $\sim 10 \times 10^{-9} \text{ g per g}$; this represents typically an average over the upper few metres or so of the regolith. After a study of the overall character of the trace-element abundance patterns, this enrichment has been attributed^{10,11} to the addition of carbonaceous chondrite-like material at a rate of the order of $4 \times 10^{-9} \text{ g cm}^{-2} \text{ yr}^{-1}$ over $4.5 \times 10^9 \text{ yr}$. (The Ir concentration in chondrites is over 1,000 times that found in the crust of the Earth and 100 times that of lunar soil.) At this rate, 0.4 g cm^{-2} of the meteoritic material would be accumulated in the 10^8 year intervals between our hypothesised occurrences of intense γ -ray flashes. The rapid transfer of this amount of meteoritic matter alone to the surface of the Earth would provide 0.03 g cm^{-2} which, when mixed into 1 g cm^{-2} of terrestrial soil, would yield an Ir concentration of about $15 \times 10^{-9} \text{ g per g}$. However, turnover of lunar surface

matter occurs at a rate given approximately by 0.1 cm Myr^{-1} (ref. 8). If there were mixing to a depth of several centimetres over a 10^8 year interval, the average Ir content of this surface material would be of the order of $3 \times 10^{-8} \text{ g per g}$. There is no compelling reasons for the lunar surface to be homogeneous: some patches may have more than this while most probably have less. The Ir results obtained by Alvarez *et al.*⁷ might be understood in this way only if the top several g cm^{-2} of lunar soil were evaporated and now contributed the measured Ir at the appropriate geological stratum. Alternatively, we might assume the top g cm^{-2} has a significantly higher average value, $\sim 10^{-7} \text{ g per g}$, since there might be large patches which do not undergo such thorough mixing before evaporation. If most of this material reached the Earth and mixed with 1 g cm^{-2} , the Ir discontinuity obtained at Gubbio could again follow, but its magnitude does seem much larger than is easily explained by lunar surface matter transfer.

Orbits of near Earth micrometeoritic particles will be strongly altered by non-symmetric surface evaporation resulting from a γ -ray flash. This too may cause a temporary increase in the fall of very Ir rich matter onto the Earth (A. Fabian, personal communication).

A $10^{10} \text{ erg cm}^{-2}$ flash would lead directly to very strong ozone suppression in the Earth's atmosphere, and thus very greatly increased solar UV radiation at the Earth's surface for about a decade⁵. In addition, during the long period of lunar soil mass transfer through our atmosphere, the transparency of the dirtied terrestrial atmosphere to visible and Ir radiation would be very greatly altered, even if the lunar matter remained mainly gaseous. The added lunar matter could be almost a tenth as abundant as atmospheric CO_2 . If the lunar matter were dustlike, the direct atmospheric albedo together with changed cloud seeding would significantly influence the surface climate.

The detailed consequences of these various possible environmental modifications on biological species are not known. It seems reasonable to speculate that a biological cataclysm may have resulted. A key question is whether or not the great extinctions at the end of the Cretaceous age in which approximately one-quarter of all species, including the dinosaurs, died were sufficiently simultaneous¹². Some recent data incorporating times of magnetic field reversals have been interpreted as indicating that the faunal overturn at Gubbio took $<10^4 \text{ yr}$ (ref. 13) and that the Foraminifera and dinosaur extinctions in Alberta were 'simultaneous' with a maximum error of 10^5 yr (ref. 14). While such data hardly insist on a sudden catastrophic explanation, they do question the notion that there are no strong correlations among the extinctions or that they are all caused by slowly changing geological conditions.

Reactions of OH radicals with gaseous sulphur compounds

R. A. Cox

Environmental and Medical Sciences Division, AERE, Harwell, Oxfordshire OX11 0RA, UK

D. Sheppard

Department of Chemistry, University of Birmingham, Birmingham B15 2TT, UK

Several recent papers¹⁻³ have discussed the origin of the sulphate aerosol in the stratosphere in terms of atmospheric carbonyl sulphide (OCS) and carbon disulphide (CS₂). There is, however, considerable uncertainty in the life cycles and budgets of these compounds. This arises from a lack of knowledge of the various possible sources and also from the differences in the reported rate constants for the reactions of OCS and CS₂ with hydroxyl (OH) radicals^{4,5}, which provide a potentially large sink for these molecules in the troposphere. We report here measurements of rate constants and product formation for OH reaction with several sulphur compounds, including OCS and CS₂. The results support the suggestion that oxidation of CS₂ is a significant source of atmospheric OCS, but do not give conclusive evidence for a large sink for OCS in the troposphere.

Interest in atmospheric sulphur chemistry has recently focused on the sulphate component in the stratospheric aerosol layer which plays a significant role in the Earth's radiation budget. In addition to direct injection of SO₂ into the stratosphere from volcanic activity, an important role for OCS as a carrier of sulphur from the troposphere to the stratosphere has been suggested¹. Recent measurements⁶⁻⁹ show that OCS is indeed widely distributed in the atmosphere. Photolysis of OCS in the stratosphere releases atomic S which is oxidised and subsequently converted to H₂SO₄ aerosol. It has also been proposed that reaction of OCS with OH is the origin of the SO₂ present in the background troposphere¹⁰ and that a similar reaction of CS₂ is a source of atmospheric OCS as well as SO₂ (ref. 2).

In the present work rate constants were measured using a competitive rate technique, in pseudo-atmospheric conditions. Hydroxyl radicals were generated by the photolysis at 350 nm of ~5 p.p.m. of nitrous acid (HONO) in synthetic air at 1 atm pressure and ambient temperature (297 ± 2K), contained in a 200 l bag fabricated of Tedlar film. Photolysis of the mixture results in a steady state concentration of OH radicals which at small conversion is governed by the reactions (1) and (2)¹¹

[OH] can be conveniently monitored in this system by addition of a few p.p.m. of ethylene (C₂H₄) which, following attack by OH, is oxidised to two molecules of formaldehyde by a chain reaction in which OH is regenerated^{12,13}. By monitoring the rate of C₂H₄ decay, [OH] can be calculated from the relationship

$$-\frac{d \ln [\text{C}_2\text{H}_4]}{dt} = k_3 [\text{OH}] \quad (3)$$

k_3 is the rate constant for the reaction of OH + C₂H₄ which at atmospheric pressure has a value of $8 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$

(ref. 14). Rate constants for the reaction of OH with the sulphur compounds were obtained relative to k_3 , by measurement of the decay of the sulphur compound and of C₂H₄ during photolysis in the HONO-Air mixtures for ~30 min. Expressing the integrated forms of equation (3) as ratios for the two substrates gives

$$\ln \frac{[\text{S}]_0}{[\text{S}]_t} = \frac{k_s}{k_3} \ln \frac{[\text{C}_2\text{H}_4]_0}{[\text{C}_2\text{H}_4]_t} \quad (4)$$

where the subscripts refer to concentrations at time 0 and t ; k_s is the rate constant for reaction of OH with the sulphur compound, S.

Ethylene, methyl mercaptan (MM), dimethylsulphide (DMS), dimethyldisulphide (DMDS) were all measured by gas chromatography using flame ionisation detection. H₂S, SO₂, OCS and CS₂ were measured using a flame photometric detector after separation on a 1 m Chromasil 316 column mounted in an all-PTFE chromatographic system. HONO, NO and NO₂ were measured using a commercial chemiluminescence detector. All gases and vapours were used as supplied commercially except for OCS from which H₂S impurity was removed to a level of <0.01% by passage through aqueous Cu(NO₃)₂.

Figure 1 shows a plot of the concentration-time data according to equation (4). Good straight line plots were obtained in the main, indicating that the removal of both substrates was dominated by reaction with OH. For CS₂ and DMS there was a tendency for their removal rates to increase relative to C₂H₄ later in the reaction. This can be attributed in part to reaction with oxygen atoms, which are produced from photolysis of NO₂ formed during photolysis. Also CS₂ absorbs light in the 300–350 nm region; in the absence of HONO, the decay rate of CS₂ was a factor of 3 slower indicating that although direct photolysis was significant in the HONO-CS₂ system, it was not the major decay route for CS₂.

Table 1 Rate constants for OH + sulphur compounds

Gas	$\frac{k_s}{k_{\text{C}_2\text{H}_4}}$	$k_s (\text{cm}^3 \text{ molecule}^{-1} \text{ s}^{-1} \times 10^{-12})^*$
DMDS	28 ± 10	223 ± 80
MM	11.3 ± 1.1	90.4 ± 8.5
DMS	1.14 ± 0.18	9.1 ± 1.4
H ₂ S	0.62 ± 0.04	5.0 ± 0.3
SO ₂	0.09 ± 0.02	0.72 ± 0.16
CS ₂	0.06 ± 0.02	0.43 ± 0.16
OCS	≤ 0.005	≤ 4 × 10 ⁻²

* Using $k_{\text{C}_2\text{H}_4} = 8 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$.

Table 1 shows a summary of the rate constant data from the plots according to equation (4). The OH rate constants are in good agreement with previous results for SO₂ (at 1 atm pressure)¹⁵, H₂S (refs 15, 16) and DMS (ref. 14). A value for k (OH + DMDS) has not apparently been reported before. For both CS₂ and MM the values are both higher than measured directly using the resonance fluorescence technique at low total pressures^{4,5,14}. We conclude that the reaction of OH with MM is enhanced at high pressure. The position for CS₂ is less well defined; the CS₂ value given has been corrected for the apparent contribution of ~40% to the CS₂ decay, due to photolysis and O(³P) reaction, but the possibility of a systematic error in this determination cannot be entirely ruled out. We are, therefore, unable to conclude definitely whether there is a pressure effect on $k(\text{OH} + \text{CS}_2)$ but our results are certainly more consistent with the value reported by Kurylo⁵ that is, $1.8 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ than with the upper limit value of Atkinson *et al.*⁴, $7 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$.

For OCS, the absence of any measurable decay gave an upper limit comparable with the largest reported value for $k(\text{OH} +$

OCS) (ref. 5), that is, $5.66 \times 10^{-14} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. However, observation of the effect of a large excess of OCS on the apparent $[\text{OH}]$ calculated from equation (3) in the $\text{HONO}-\text{C}_2\text{H}_4$ system, indicated that the true value of $k(\text{OH} + \text{OCS})$ may be considerably lower than this upper limit. A value of $\sim 8 \times 10^{-15} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ could be derived from the data but uncertainties in the detailed chemistry precluded an accurate determination of this rate constant.

Fig. 1 Plot of $\ln [S]_0/[S]$, versus $\ln [C_2H_4]_0/[C_2H_4]$, for the decay of sulphur compounds and ethylene during photolysis in HONO/air mixtures at atmospheric pressure and 297 K.

Investigation of product formation in these systems revealed that SO_2 is a major product in the reaction of OH with all the S compounds investigated, with the exception of SO_2 itself which is oxidised to an H_2SO_4 aerosol¹⁷. H_2S was converted quantitatively to SO_2 and, as the initial attack of OH with H_2S undisputably occurs through the reaction

we conclude that HS is efficiently converted to SO_2 in our experimental conditions. The observation of SO_2 formation in the $\text{OH} + \text{CS}_2$ and $\text{OH} + \text{OCS}$ system therefore supports the suggestion⁵ that these reactions proceed through an addition complex, which yields HS as a primary product:

Further indication that this is a major pathway for CS_2 comes from the observation of the production of OCS with a high yield ($\sim 100\%$) in the $\text{OH} + \text{CS}_2$ system.

Note the significance of the results in the context of the behaviour of CS_2 , OCS and the organic sulphides in the global

sulphur cycle. The ubiquitous presence of OH in the troposphere provides a sink mechanism for gases with which it reacts. A relationship between tropospheric lifetime and OH reaction rates has been computed using a two-dimensional model¹⁸; our value of $k(\text{OH} + \text{CS}_2)$, that is, $4.3 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ gives a lifetime of 0.2 yr for CS_2 .

Our results show that the reaction of CS_2 with OH radicals provides a potentially large source of OCS in the troposphere. The major uncertainty in the calculation of the source strength is due to the paucity of observational data for atmospheric CS_2 . The only reported measurements of CS_2 in air⁷, gave concentrations in the range 0.07–0.37 p.p.b. (parts per 10⁹). Subsequent measurements have confirmed that CS_2 concentrations near the lower end of this range are normally present in the atmosphere at Harwell (S. A. Penkett, personal communication). If the value of 0.07 p.p.b. is taken to be representative of background tropospheric air, the source strength of OCS corresponding to a lifetime of 0.2 yr is $2 \times 10^{12} \text{ g(S) yr}^{-1}$. This is considerably larger than estimates of OCS emissions from identified sources, that is, biomass burning, $2.4 \times 10^{11} \text{ g(S) yr}^{-1}$ (ref. 19), soil emissions $2.3 \times 10^{11} \text{ g(S) yr}^{-1}$ (based on flux measurements in the US²⁰).

The source of OCS from CS_2 alone is considerably larger than estimates of the amount of OCS removed by photolysis in the stratosphere^{1,2}, $(2-5) \times 10^{10} \text{ g(S) yr}^{-1}$, and implies a large sink for OCS in the troposphere. Measurements⁶⁻⁹ of tropospheric OCS have shown that it is fairly uniformly distributed with a concentration of about 0.4 ± 0.1 p.p.b., and, to balance the source from CS_2 , would require a lifetime of 1.1 yr for OCS. A sink of this magnitude could be provided by reaction with OH only if the 'high' value for the rate constant $k(\text{OH} + \text{OCS})$ (ref. 5) was correct. However, the true value may be lower by up to a factor of 10, which suggests that an additional sink for OCS may be operative. Physical removal of OCS on vegetation²¹ or at ocean surfaces may fulfil this role.

The reaction of OH with CS_2 as formulated above also provides a source of SO_2 , equivalent in size to that of OCS. In this case, however, the source is small compared with the global flux of sulphur in the troposphere $1 \times 10^{14} \text{ g(S) yr}^{-1}$ (ref. 22) of which about 60% is due to SO_2 emission from fossil fuel combustion. The remainder of the tropospheric sulphur is thought to originate from oxidation of H_2S , DMS and other organic sulphur compounds, primarily of natural origin. The present work confirms their short tropospheric lifetime due to rapid reaction with OH, and also shows that SO_2 is an important product of these reactions in pseudo-atmospheric conditions.

Enrichment of ^{210}Pb and ^{210}Po in the sea-surface microlayer

Michael P. Bacon & Alan W. Elzerman*

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543

Chemical fractionation at the air-sea interface is frequently suggested¹⁻⁵ as a possible mechanism contributing to the enrichment of a number of trace metals in the marine atmosphere^{6,7}. The origin of the long-lived radon daughters (^{210}Pb , ^{210}Bi and ^{210}Po) in the atmosphere is of special interest because of their use in the estimation of tropospheric aerosol residence times⁸. It has been proposed⁹ that injection of a fractionated marine component by bubbles bursting at the sea surface might be responsible for the occurrence of anomalously high atmospheric $^{210}\text{Po}/^{210}\text{Pb}$ ratios in Antarctica¹⁰ and Hawaii¹¹. Here we report the first measurements of ^{210}Pb ($t_{1/2} = 22.3$ yr) and ^{210}Po ($t_{1/2} = 138$ d) in the sea-surface microlayer. These measurements were made to determine whether or not a significant flux of these radionuclides from the sea surface to the atmosphere could occur. We also introduce a method for treating chemical data that we believe may be useful in determining the origin of the trace-metal enrichments often observed^{1,2} in the microlayer.

The sea-surface microlayer is the uppermost thin skin of the oceanic water column. It is often characterised by anomalously high concentrations of heavy metals and other trace substances thought to be associated with particulate matter and surface-active organic material^{1,2}. The thickness of the microlayer is defined by the method used to sample it. We used a plastic screen in a modification of the technique of Garrett which samples the upper 300 ± 50 μm (refs 12, 13). Because this was an initial attempt to detect enrichments of ^{210}Pb and ^{210}Po in the microlayer, we deliberately chose to collect our screen samples in calm sea conditions when visible surface slicks were present. Bulk surface-water samples were collected by immersing polyethylene jugs to a depth of about 20 cm and allowing them to fill. We also analysed a single sample of foam collected along the shore of a coastal pond. This material is believed to represent a more concentrated example of the anomalously enriched layer than samples provided by the screen technique^{14,15}. Details of the analytical procedures are given elsewhere¹⁶.

Results are shown in Table 1. In all cases both ^{210}Pb and ^{210}Po showed enrichments in the sea-surface microlayer samples in comparison with bulk surface-water samples. The degree of enrichment seemed to correlate with film pressure (depression of surface tension) estimated by the oil-drop method^{13,17}, although film pressures were always near the limit of detection. The greatest enrichments occurred in the foam sample from Oyster Pond. Thus a correlation exists between enrichments of the radionuclides and the presence of surface-active material.

To assess the role of the sea surface in supplying metal-rich aerosols, one must determine whether the enrichments in the microlayer are maintained by deposition of atmospheric material or by concentration of the metals from seawater. Only in the latter case can the sea act as a source. The $^{210}\text{Po}/^{210}\text{Pb}$ activity ratio may provide an important clue. Table 2 lists representative values of the $^{210}\text{Po}/^{210}\text{Pb}$ ratio in atmospheric fallout and in seawater and marine particulate matter from both coastal and open-ocean environments. The atmospheric ratio is much lower than the ratios in bulk surface seawater measured in this study, yet the $^{210}\text{Po}/^{210}\text{Pb}$ ratios in the microlayer samples show only small departures from the bulk seawater values. This comparison suggests that the ocean may be an important source of the enrichments found in the microlayer.

A more quantitative treatment of this question can be made by consideration of a simple model in which the surface-microlayer enrichment consists of two components: an atmospheric component and an oceanic component supplied by concentration from seawater and upward transport to the air-water interface. This latter supply process may involve chemical fractionation. It is assumed that processes removing material from the microlayer, either physical injection into the atmosphere or mixing downward in the water column, involve no chemical fractionation. With this assumption we can write for ^{210}Pb :

$$\Delta_{\text{Pb}} = \text{Pb}_m - \text{Pb}_b = \varepsilon_{\text{Pb}} \text{Pb}_b + \text{Pb}_a \quad (1)$$

where the ^{210}Pb enrichment, Δ_{Pb} , is the difference between the ^{210}Pb concentration in the microlayer, Pb_m , and the concentration in bulk surface seawater, Pb_b . This concentration difference consists of an enriched oceanic component, $\varepsilon_{\text{Pb}} \text{Pb}_b$, and an atmospheric component, Pb_a . A similar equation can be written for ^{210}Po :

$$\Delta_{\text{Po}} = \text{Po}_m - \text{Po}_b = \varepsilon_{\text{Po}} \text{Po}_b + \text{Po}_a \quad (2)$$

Finally we assume that the atmospheric $^{210}\text{Po}/^{210}\text{Pb}$ ratio, R_a , is known:

$$R_a = \text{Po}_a / \text{Pb}_a \quad (3)$$

Equations (1)–(3) contain four unknown quantities, so it is not possible to solve them uniquely. It is possible, however, to derive a relationship between two important quantities. Let α denote the fractionation between ^{210}Pb and ^{210}Po during their transport from bulk seawater to the microlayer. This fractionation is given by

$$\alpha = \varepsilon_{\text{Po}} / \varepsilon_{\text{Pb}} \quad (4)$$

so if $\alpha > 1$, then ^{210}Po is preferentially (relative to ^{210}Pb) transported to the microlayer. This condition is probably necessary if the sea surface is to act as a source for the anomalously high $^{210}\text{Po}/^{210}\text{Pb}$ ratios in Antarctic aerosols¹⁰, because $^{210}\text{Po}/^{210}\text{Pb} < 1$ in most ocean surface water. (Coastal waters in Vineyard Sound (Table 1) and other locations^{18,19} are often the exception with $^{210}\text{Po}/^{210}\text{Pb} > 1$. The origin of the unsupported ^{210}Po in these waters is not understood. Over most of the ocean surface,

Fig. 1 Results of the model calculations for $R_a = 0.1$. Each screen sample is represented by a curve. In those cases for which more than one bulk surface-water sample was collected on the same date and in the same location, the results from Table 1 were averaged. For $\alpha = 1$ there is no chemical fractionation. For $f = 1$ all of the enrichment of ^{210}Pb in the microlayer is contributed from the atmosphere. The curves are fairly insensitive to variations of R_a in the range 0–0.2.

* Uncertainties listed are standard errors based on counting statistics.

† These are approximate values. All measurements were near the detection limit, and there was often some variation in film pressure during each sampling period because of slick patchiness.

however, $^{210}\text{Po}/^{210}\text{Pb} < 1$ because of biological uptake and transport of ^{210}Po to deeper water²⁰. We now let f denote the fraction of the microlayer ^{210}Pb enrichment that is contributed from the atmosphere, and we can write

$$f = \text{Pb}_a / (\text{Pb}_a + \text{Pb}_b) \quad (5)$$

With these definitions and with equations (1)–(3), we derive the following equation:

$$\alpha = (\Delta\text{Po}/\Delta\text{Pb} - fR_a) / (1 - f)R_b \quad (6)$$

where $R_b = \text{Po}_b/\text{Pb}_b$. Thus for any microlayer/bulk-seawater sample pair we can define a relationship between α and f . Note that this relationship is independent of the degree of dilution of the microlayer sample by bulk seawater.

Figure 1 shows curves based on equation (6) and the data in Table 1. Although our data do not allow a unique solution, the curves in Fig. 1 allow some limitations to be placed on their interpretation. We note that as f approaches a value of 1.0 (no oceanic contribution), α increases very rapidly. In other words, the more dominant the atmospheric contribution to the microlayer enrichment of ^{210}Pb becomes, the more strongly fractionated the oceanic contribution must be to compensate for the low $^{210}\text{Po}/^{210}\text{Pb}$ ratio in the atmospheric component. We believe that a reasonable interpretation of the data requires that at least part of the microlayer enrichments be supplied by concentration of ^{210}Pb and ^{210}Po from the bulk seawater.

At the other extreme, by setting $f = 0$ (no contribution from the atmosphere), we obtain the minimum possible value for α . To explain our open-ocean results (samples NA-1 and NA-2), we require $\alpha > 1$ no matter how small a value is assumed for f ; that is, concentration of ^{210}Pb and ^{210}Po from the bulk seawater must involve chemical fractionation such that ^{210}Po is preferentially transported to the interface. For the coastal water samples (sample OP-1 and the VS samples), $\alpha \approx 1$ (little or no fractionation) if no atmospheric contribution is assumed. This reflects the similarity of $^{210}\text{Po}/^{210}\text{Pb}$ ratios in microlayer and bulk surface-water samples at the coastal sampling sites. Only for $f \geq 0.4$ must significant fractionation be postulated.

Experiments in which columns of seawater are bubbled with air suggest that trace-metal enrichments in the microlayer may be maintained by transport of particulate matter to the interface⁵. If this were the predominant mechanism for ^{210}Pb and ^{210}Po , and if it acted indiscriminately for all types of particulate matter, then it would be possible to estimate α from the known distribution of ^{210}Pb and ^{210}Po between dissolved and particulate forms in surface seawater by using the expression

$$\alpha = (^{210}\text{Po}/^{210}\text{Pb})_{\text{particulate matter}} / (^{210}\text{Po}/^{210}\text{Pb})_{\text{bulk seawater}} \quad (7)$$

In open-ocean surface water^{21,22} this quantity is in the range 2.4–8.8 (median 6.7). Coastal surface waters (ref. 18 and unpublished data) are characterised by values closer to 1.0, probably because of the contribution of resuspended bottom sediment to the particulate matter. This difference may account for the segregation of our open-ocean samples from our coastal samples (Fig. 1), but further testing of this hypothesis is required.

We have shown that the sea-surface microlayer is enriched in ^{210}Pb and ^{210}Po . Our interpretation of the data suggests that a significant fraction of the enrichment is maintained by concentration from the bulk surface seawater. In the open ocean this concentration process results in preferential transport of ^{210}Po to the air–sea interface. In coastal environments there may be a

Table 2 Representative values of the $^{210}\text{Po}/^{210}\text{Pb}$ activity ratio in seawater, marine particulate matter and atmospheric fallout

lesser degree of chemical fractionation. Because coastal waters often have $^{210}\text{Po}/^{210}\text{Pb}$ activity ratios > 1 , the sea surface is, in either case, a potential source of aerosols with $^{210}\text{Po}/^{210}\text{Pb} > 1$ as suggested by Turekian *et al.*⁹. The natural flux of microlayer material from the sea to the atmosphere, however, is not known.

Note finally that our analytical treatment of the microlayer enrichments was limited because only two elements were used. Further analysis by a multi-element approach is suggested.

We thank K. K. Turekian and O. C. Zafiriou for helpful comments. This research was supported by US Department of Energy Contract AT(11-1)3566 and by a Postdoctoral Scholar Award to A. W. Elzerman from the Woods Hole Oceanographic Institution.

Self-reversal of natural remanent magnetisation in the Olby-Laschamp lavas

Friedrich Heller

Institut für Geophysik, ETH-Hönggerberg, CH-8093 Zürich, Switzerland

In 1967 Bonhommet and Babkine¹ reported reversed magnetisation directions in two lavas at Laschamp and Olby (Chaîne des Puys, Auvergne, France). They argued that the remanent magnetisation might have originated either from an episode of reversed polarity of the geomagnetic field within the Brunhes normal epoch or from a process of self-reversal² occurring in these lavas. I report here experimental evidence that the natural remanent magnetisation (NRM) of certain samples of the Olby flow undergoes complete self-reversal during thermal demagnetisation. Other Olby samples show partial self-reversal of NRM at room temperature.

Radiometric dating initially gave age limits to the extrusion of the Laschamp and Olby basalts between 8,000 yr and 20,000 yr BP (ref. 3) and since then the reversed volcanics have been generally accepted as a well documented case of a recent excursion of the Earth's magnetic field⁴, named the 'Laschamp geomagnetic polarity event'. Although Denham and Cox⁵ proved that it was highly probable that the geomagnetic field remained constantly normal on a global scale between 13,300 and 30,400 yr BP, many authors^{6–11} tried to correlate other events such as the Gothenburg⁶, Gulf of Mexico⁷, Maelifell¹⁰, Erieau¹¹ excursions with the Laschamp reversal. Age dating techniques have recently been refined. As a result of new K–Ar, $^{40}\text{Ar}/^{39}\text{Ar}$, $^{230}\text{Th}/^{238}\text{U}$ and thermoluminescence dates^{4,12–14} it

seems likely that the true age of the 'Laschamp event' is between 40,000 and 45,000 yr BP. Consequently magnetic correlation is now being made with somewhat older reported excursions, such as the Lake Mungo¹⁵ or Lake Biwa¹⁶ records.

Whatever the significance of these correlation attempts, the importance of geomagnetic events or excursions as magneto-stratigraphic marker horizons is unquestioned. Nevertheless, I would like to put forward an alternative explanation for the Laschamp event. Thermomagnetic experiments performed on the reversely magnetised Olby flow demonstrate that a self-reversal process acts on its NRM.

The occurrence of self-reversal in igneous rocks has long been debated. Extensive investigations have been postponed because of the overwhelming evidence that reversely magnetised rocks generally were magnetised by the Earth's field in a reversed polarity state. However, a few examples of self-reversal of the NRM in volcanic rocks have been reported: the Haruna dacite in Japan¹⁷, certain oceanic basalts^{18,19} and a basalt from Germany²⁰. Partial self-reversal leading only to a reduction of NRM intensity at room temperature, but not to a completely antiparallel alignment of the NRM direction with respect to the ambient geomagnetic field, was observed in an historical lava flow of Mount Etna²¹. Furthermore it has been shown in continental basalts^{22–24} that thermoremanent magnetisation (TRM) produced during moderate heat treatment in the laboratory can acquire self-reversal or at least partial self-reversal characteristics at room temperature.

Self-reversal processes can be classified into three categories according to different physical mechanisms: (1) A one-constituent model in which the direction of spontaneous magnetisation changes sign at a certain temperature (Néel's²⁵ P- or N-type ferrimagnets). (2) A two-constituent model in which negative exchange interaction across the boundary of two magnetic phases plays the essential role. (3) A two-constituent model in which magnetostatic interaction between two phases leads to complete or partial self-reversal of remanence.

I have sampled the reversed basalts of Laschamp (site F³) and Olby (site B³), and one normally magnetised flow to the west of Puy de Barme. The NRM directions obtained after alternating field cleaning are similar to those observed by Bonhommet²⁶, but also some normal samples have been found in the reversed

Fig. 1 Partial self-reversal of natural remanent magnetisation during heat treatment in four basalt samples collected from the reversed Olby flow. Heating rate, $10^\circ\text{C min}^{-1}$.

Fig. 2 Complete self-reversal of natural remanent magnetisation of an Olby basalt sample (QB 2 BC) during thermal treatment. Inclination, declination and intensity have been plotted separately against temperature. Three heating and cooling cycles follow each other. Note, the sharp peaks of the intensity curve around 200 °C are caused by the self-reversal process which leads to a normal remanence direction below 50 °C in all three cooling cycles. Above 200 °C the remanence direction is reversed and antiparallel to the room temperature direction.

Olby flow. Rockmagnetic studies by Whitney *et al.*²⁷ reported that both reversed lavas are highly oxidised without any indication of a self-reversal of NRM. My observations are that the rock-magnetic properties and other physical parameters (for example, oxidation state, porosity) of the lavas investigated vary to a large extent from flow to flow as well as within the flows.

The magnetic properties of the reversely magnetised Olby flow are particularly interesting and show that the NRM of at least this flow has self-reversal characteristics. Several samples of the flow have been subjected to continuous thermal demagnetisation²⁸. Figure 1 shows the NRM intensity behaviour during thermal treatment of four Olby samples which, before this experiment, were a.f.-cleaned in fields of up to 10 mT to remove secondary soft components. Up to 200 °C all samples show a peculiar increase in intensity amounting to up to 50% of the initial value. No directional NRM changes are observed during heating up to 550 °C. Sample 2CC shows that the demagnetisation curve is repeatable between 100 and 350 °C when the temperature is lowered and raised again. Therefore the initial intensity increase can be explained only by a partial self-reversal process acting in these samples. Below 200 °C an apparently normal NRM component is coupled to the pre-dominant reversed magnetisation the intensity of which is reduced in this way at room temperature.

Using the same demagnetisation technique as in Fig. 1, a complete self-reversal of NRM has been found in another Olby flow sample (Fig. 2). During the first heating a soft, viscous magnetisation component of normal polarity is removed up to 200 °C. This component obscures the behaviour of the stable NRM components in this temperature range. Further heating to 400 °C reduces the intensity, but leaves a stable reversed NRM direction which has a southwesterly declination and steeply

negative inclination as found often in the Olby flows²⁶. When cooling from 400 °C to room temperature in zero magnetic field ($H < 20$ nT) at first an intensity increase is observed till 170 °C which is followed by a sharp decrease in NRM intensity. At 150 °C the declination component begins to change direction. At about 40 °C the magnetisation changes sign and a normal NRM is built up roughly antiparallel to the former NRM direction. The same features are recognised in the subsequent second and third heating and cooling cycle (Fig. 2), where, during heat treatment, the NRM changes sign at temperatures between 50 and 70 °C. Thus, although their magnetisation behaviour is different, all three cycles lead to a complete self-reversal in this Olby flow sample.

At the present stage of investigation a unique answer to the self-reversal process itself cannot be given: one-phase or two-phase models may apply. On the basis of ore microscopic observation and thermal demagnetisation characteristics of NRM a two-constituent model is currently preferred. In contrast to earlier findings²⁷ I have optically identified only low temperature oxidised titanomagnetite in these Olby flow samples. Therefore the thermomagnetic curves may be controlled by two magnetic phases with different Curie temperatures (T_c): a titanomagnetite with $T_c \approx 180$ °C and a titanomaghemite with $T_c \approx 350$ °C (see Fig. 2). The sharp drop in NRM intensity during heating and cooling around 200 °C is caused by the reversal process, but seems to be incompatible with P-type magnetisation curves because of its peaked appearance. The disappearance of the sharp magnetisation peak at 200 °C during cooling in the third cycle may indicate that the Ti-maghemite has been destroyed by heating to near 500 °C. Thus a negative magnetic interaction between two phases may cause complete or partial self-reversal of NRM in experimental conditions. It still has to be shown that such an interaction took place during the original NRM formation. However, if the titanomagnetite formed at temperatures below 180 °C by low temperature oxidation, such a process would lead to a reversed NRM direction in the Olby flow in the presence of a normal geomagnetic field direction.

The reversely magnetised Laschamp flow carries highly oxidised titanomagnetite and complete self-reversal of NRM during laboratory experiments has not yet been proved. However, this lack does not dismiss the possibility of self-reversal for this flow, in particular as recent investigations²⁹ have demonstrated that self-reversal may occur in strongly oxidised titanomagnetite, but may not be reproducible by laboratory experiment.

The present experiments recall strongly the need for thorough rock-magnetic investigations³⁰ when ascribing reversed magnetisation directions in igneous rocks to reversals of the geomagnetic field.

Palaeomagnetic constraints on Greater India's underthrusting of the Tibetan Plateau

Douglas K. Bingham* & Chris T. Klootwijk

Research School of Earth Sciences, Australian National University, PO Box 4, Canberra A.C.T. 2600, Australia

A minimum estimate of the magnitude of Greater India's underthrusting along the Main Central Thrust beneath its former leading edge and beneath the Tibetan Plateau to the north is reported here. A comparison of newly obtained late Palaeozoic and Mesozoic palaeomagnetic results from the Tibetan Sedimentary Series (Thakkhola Graben, north central Nepal) with results from the Indian subcontinent indicates an excess anticlockwise rotational movement of Greater India with respect to its former leading edge of 10–15°. Assuming that the pivot point for this differential rotation is located to the west of the Western Himalayan Syntaxis, this magnitude corresponds to a minimum underthrusting of continental lithosphere of 200–350 km at the longitude of central Nepal.

Large scale underthrusting of Greater India beneath the Tibetan Plateau has been postulated repeatedly on geological^{1–3} and geophysical grounds^{3,4} to explain the thickness of the crust beneath the Tibetan Plateau, about twice as thick as the average continental crust. This postulate conflicts with the established notion that buoyancy constraints^{5,6} preclude large scale subduction of continental lithosphere. Recent studies⁷ suggest, however, that such subduction over several hundred kilometres may be possible within the range of plausible values for model parameters.

The magnitude of Greater India's underthrusting beneath Asia can be constrained palaeomagnetically. Favourable conditions are: (1) northwards-directed underthrusting proceeded at first beneath Greater India's former leading edge which is preserved at the surface and can be studied; and (2) underthrusting resulted largely from an anticlockwise rotational

movement whose magnitude can be determined relatively easily. Besides, understanding of the evolution of the India–Asia collision has advanced considerably in recent times. Mutually supporting geological data^{3,8,9}, seafloor spreading analyses^{3,10,11}, and palaeomagnetic data^{12–14} indicate conclusively that welding of India to Asia along the Indus–Tsangpo suture zone (Fig. 1) occurred from about the late Palaeocene until maybe the late Eocene. Continental subduction during this phase was probably only of a minor magnitude^{3,8}. After the intimate contact had been established, the Indus–Tsangpo suture zone became immobilised and the India–Asia convergence slowed down considerably. A new zone of weakness developed about 100–200 km further to the south within Greater India and this zone evolved into the Main Central Thrust. Renewed convergence of intracontinental character occurred along the Main Central Thrust since possibly the Oligocene^{9,11}. Greater India thus underthrust its former leading edge and beyond, beneath the Tibetan Plateau. Powell and Conaghan^{3,4} postulated initially that Greater India's underthrusting may have proceeded beneath the full width of the Tibetan Plateau (over ~1,500 km at the longitude of far eastern Nepal). Powell¹¹, however, has recently reduced this estimate considerably.

Seafloor spreading analyses^{10,11,15–17} show that post-collisional convergence of India with Asia was characterised by an appreciable anticlockwise rotational movement of the Indian plate with respect to Asia. This can be interpreted as the main cause for the development of the pronounced asymmetrical pattern plan of the Himalaya^{11,18,19}. Our estimate for the magnitude of underthrusting along the Main Central Thrust is based on a comparison of newly obtained palaeomagnetic results from the former leading edge of Greater India with palaeomagnetic results from the Indian subcontinent (summarised in ref. 14). This method is particularly suited for the determination of the rotational component of underthrusting, but is much less precise in the determination of a possible northwards translational component of underthrusting.

Palaeomagnetic results representative of Greater India's former leading edge were obtained from late Palaeozoic and Mesozoic carbonates and sandstones from the Tibetan Sedimentary Series of the Thakkhola Graben, North Central Nepal. This region was chosen because of its relatively easy access, its detailed geological mapping^{20–22}, and the much lower degree of metamorphism than is prevalent in adjacent regions of the Tibetan Himalaya. Moreover, the Main Central Thrust is parti-

Thini Chu Fm.	M?Permian	41 (40)	291.5	–63.5	10	7.5	16

Mean directions and statistical parameters were obtained according to ref. 38.

*Formation names and ages are according to refs 22, 28 and according to ref. 37 for the sampled part of the Thini Chu Fm.

†The number of specimens wherein the component concerned could be identified. The number of samples collected are in parentheses.

cularly well developed, and has been studied thoroughly²² in the region south of the sampled location.

A summary of significant palaeomagnetic data is given in Table 1; a more detailed account of results will be presented elsewhere (our work, in preparation). Altogether more than 750 core samples were drilled from cliff sections bordering the Kali Gandaki river in the tract between Shang (28°45'N 83°44'E) in the south and Kagbeni (28°49'N 83°46.5'E) in the north, and also in cliffs immediately north of the Muktinath sanctuary (28°48'N 83°50'E). We restricted our sampling mainly to the Mesozoic and to a lesser extent the late Palaeozoic carbonates and sandstones. These are very well exposed in a WNW–ESE trending belt situated ~10–20 km north of the main range, formed by the impressive Dhaulagiri and Nilgiri–Annapurna massifs. Middle and early Palaeozoic carbonates exposed immediately south of the sampled region, that is, in the north-face of Nilgiri, show a southwards increasing metamorphism

associated with formation of the Main Central Thrust and have not been sampled for that reason.

In general two specimens per sample were thermally demagnetised, using furnaces as described by McElhinny *et al.*²³, in about 10 steps over a temperature interval determined on the basis of more elaborate pilot demagnetisation studies. The directional content of the specimens was analysed from Zijderveld plots²⁴. Directions of characteristic components were determined using a principal component analysis program adapted from Kirschvink²⁵. Simultaneous breakdown of a multicomponent system of directions was fairly commonly observed in the carbonates. Whenever such specimens failed to respond satisfactorily to the Zijderveld-type analysis we analysed them subsequently for cryptic components with non-unique blocking temperature spectra²⁶, following Kirschvink's²⁵ method. Unit weight was given to specimen directions throughout the statistical analysis.

Fig. 2 Comparison of palaeomagnetic directions observed for the Thakkhola region (a) with directions expected for this region (b) according to palaeomagnetic data from the Indian subcontinent^{13,14} assuming that no relative movement between the two regions has occurred. The observed and the expected directions agree very well after correction for a 10° 'collision' component, 1–6) to a 15° (primary component, 7–16) differential rotation between the two regions (c). a, Secondary 'collision' component (1–6; 50–60 Myr) and primary components (7–16; Lower Aptian to Middle? Permian) as detailed in Table 1. b, 1, present field direction; 2, 5–22.5 Myr (DSDP); 3, 25–35 Myr (DSDP); 4, 35–45 Myr (DSDP); 5, 45–55 Myr (DSDP); 6, Sanjawi Lst. (Palaeocene–Eocene); 7 Upper Brewery Lst. (base Upper Palaeocene); 8, 55–65 Myr. (DSDP); 9, Upper Normal Deccan Traps (60–65 Myr.); 10, Lower Reversed Deccan Traps (60–65 Myr.); 11, 12, Tirupati beds (Lower Cretaceous); 13, 65–75 Myr. (DSDP); 14, Satyavedu beds (Lower Cretaceous); 15, Sylhet Traps (Lower Rajmahal Traps); 16, 17, Goru Formation–Parh Lst. (Aptian–Albian to Santonian–Campanian); 18, Rajmahal Traps (100–105 Myr.); 19, Loralai Lst. (Middle–Upper Jurassic); 20, Chiltan Lst. (Upper Jurassic); 21, Mean Middle Jurassic pole for Australia transferred to the Indian plate; 22, as above, mean Lower Jurassic pole; 23, as above for the mean Middle Jurassic pole of Antarctica; 24, Parsora beds (Upper Triassic); 25, Pachmarhi beds (Upper Triassic); 26, Kamthi beds, Wardha Valley (Permo–Triassic, 14); 28, Panchet beds (as above); 29, Kamthi beds, Wardha Valley (as above, 36); 30, Talchir beds (Permo–Carboniferous).

The specimens generally showed a fairly complex magnetic pattern. A recent field component of normal and to a lesser extent reversed polarity predominated, together with another secondary component and a primary component which were both mainly of normal polarity. Comparison with the Indian Tertiary apparent polar wander path (APWP)²⁷ shows that this secondary component stabilised between 50 and 60 Myr ago. This is also the time interval for which Krummenacher²² observed a notable resetting of K–Ar ages in central and eastern Nepal. Both the palaeomagnetic and the K–Ar data thus clearly reflect the initial collision of Greater India with southern Asia. Apart from the three magnetic components described above we also observed a west- to westnorthwestwards-directed secondary component of low downwards inclination and mainly of normal polarity. Its origin may be related to a similarly aligned pattern of *b*-axes^{22,28,29} which is well developed in the Tibetan Sedimentary Series. Secondary components of both normal and reversed polarity which originated during formation of the Main Central Thrust were dominantly present only in Carboniferous–Devonian rocks taken from the most southern sampling locality.

In the absence of contrary evidence we interpret the mean directions for the primary and secondary 'collision' components observed in the Tibetan Sedimentary Series of the Thakkhola Graben to be representative for Greater India's former leading edge, notwithstanding possible local distortions in its western extremity¹⁴. Figure 2 compares these mean directions (*a*) with the directional pattern expected for the Thakkhola region according to the Indian APWP (*b*). The observed and expected directional patterns agree very well after correction for an excess anticlockwise rotational underthrusting over 10° ('collision' component) to 15° (primary component) of Greater India with respect to its former leading edge (Fig. 2c). No clear indication for a northwards-directed translational underthrusting of Greater India beneath the Tibetan Plateau along the Main Central Thrust, or maybe along the Main Boundary Thrust³, was detectable in our palaeomagnetic results because of the inherent poor angular precision of such a determination. The asymmetrical pattern in the plan of the Himalaya^{17,18,19} indicates that the pivot point of the rotational underthrusting has to be looked for in the northwestern part of the Indian subcontinent. As a first approximation we assume its location at the western extreme of the Indus-Kohistan Seismic Zone^{30,31}. This zone represents the subsurface extension to the west of the Western Himalayan Syntaxis of the Main Boundary Thrust/Main Central Thrust complex, which thrusts, for all practical purposes, are indistinguishable from each other in the region immediately to the east of the Syntaxis. If we assume for the central and eastern part of the Himalaya that this differential rotation was restricted to rotational underthrusting along the Main Central Thrust alone, then its observed 10–15° magnitude corresponds at the longitude of central Nepal to a minimal underthrusting of 200–350 km of Greater India beneath its former leading edge and further north beneath the Tibetan Plateau.

As summarised by Molnar *et al.*¹⁹, geological, gravity and seismic data suggest an ~15° northwards dip of the Main Central Thrust. Assuming this dip to be uniform, the surface projection of the frontal part of underthrust Greater India can be located as shown in Fig. 1 according to rotational underthrusting values of 10° and 15°, respectively. Depths to the top of the frontal edge of this underthrust slab of continental lithosphere range from ~60 km in the west to ~120 km in the east taking the higher value of 15° of rotational underthrusting. It has been demonstrated³² that the calc-alkaline volcanism of island arcs is caused by melting of oceanic lithosphere at similar depths of 80–120 km. As Fig. 1 shows, there is a striking coincidence between the surface projection of the subducted slab of what in the present case happens to be continental lithosphere and a zone of Neogene to Recent calc-alkaline volcanism in southern Tibet. This zone is shown (Fig. 1) according to the 1:3,500,000 structural map of Gansser⁸, although other workers^{33–35} suggest a wider distribution of calc-alkaline volcanism. This coincidence supports our palaeomagnetic interpretation that continental

lithosphere can subduct in Himalayan-type conditions over distances of at least several hundreds of kilometres.

We thank Mike McElhinny for his support, Michel Colchen, Chris Powell, Patrick Conaghan and Bruce Waterhouse for discussions and criticism, and J. M. Tater and B. M. Pradhan for organisational support with the field work.

A man-made hot spring on the ocean floor

F. Duennebier & G. Blackinton

Hawaii Institute of Geophysics, University of Hawaii, Honolulu, Hawaii 96822

An instrument package emplaced in a deep-sea drill hole for the Glomar Challenger measured a rise in temperature at the bottom of the hole from 78°C shortly after drilling to 150°C after 42 days. The increase, not predicted by temperature measurements made before and during the drilling, is probably the result of hot water rising from below and flowing out of the hole into the ocean. We describe here this first recorded man-made hot spring on the ocean floor.

A downhole seismometer package was placed from the Glomar Challenger in DSDP hole 482-C (22°47.34' N, 107°59.57' W), located at the mouth of the Gulf of California about 12 km from the East Pacific Rise south of the Tamayo Fracture Zone¹. The hole was drilled in 3 km of water through 143 m of sediments and 47 m of massive basalt. The instrument (Fig. 1), constructed at the Hawaii Institute of Geophysics,

consists of a downhole sensor package containing thermal sensors, seismometers, tiltmeters, and associated electronics. Signals from the sensors are multiplexed and digitised into a 16-channel format for transmission by wire to a data recording and power package located on the ocean floor. The recording package is connected by floating rope to an anchor-float assembly that can be commanded to surface for data tape recovery and refurbishing of the system. A complete description of the experiment will be published elsewhere.

During the drilling, temperature was measured in the sediments with the Uyeda temperature probe, whose sensor is inserted into the sediments below the drill bit and is thus not affected by the drilling process. The temperatures show a linear trend (Fig. 2) compatible with the heat flow measurement of 12 HFU made during the site survey², if the conductivity of the sediments is assumed to be $2 \text{ mcal cm}^{-2} \text{ s}^{-1} \text{ }^{\circ}\text{C}^{-1}$. Using the same assumptions, the equilibrium temperature at the bottom of the hole should be between 90° and 110°C , depending on the conductivity of the basalt. As this value was below the design maximum of the instrument package (130°C), the sensor package was put in position on 3 February 1979.

During emplacement of the downhole seismometer package, temperature measurements were made during two time periods separated by 11 h. The first period was 30 min long and started about 7.5 h after the last water was pumped into the hole. The temperature at the end of this period was $20 \pm 2.5^{\circ}\text{C}$. By the end of the second period, 13.5 h later, the water temperature at the bottom of the hole had risen to $78 \pm 2.5^{\circ}\text{C}$, a rate of more than 4°C h^{-1} . This increase was assumed to be caused by the reheating of the hole after cooling by the drilling water.

After the second measurement period, the instrument was left to record data for 42 days and then recovered by the RV Kana Keoki on 17 March 1979. When the recording package was recovered, the sensor package was again monitored in real time. Although most of the electronics, including the multiplexer and the a to d converter were still operating, few of the sensors seemed to be working and there seemed to be little value in keeping the system operating. Therefore, the sensor package was removed from the hole. The package showed obvious signs of excessive heat; both tiltmeters had exploded, and

Fig. 2 Extrapolation of temperature measurements made while drilling (▲) yielded a temperature of about 100°C at the bottom of the hole. After 42 days, however, the temperature measured at the bottom (★) was about 150°C .

components and circuit boards that had been green before emplacement were now dark brown. Two components had mechanically shifted during emplacement, causing electrical short circuits through seawater to the recording package; however, the temperature sensors and circuitry were apparently undamaged. Although no data were obtained from the recording package, an additional 30 min of temperature information obtained during recovery showed that the temperature had risen dramatically during the time since emplacement. Because the temperature measurement obtained during recovery was greater than the maximum temperature for which the system had been calibrated (130°C), the sensor package was recalibrated at temperatures up to 155°C on its return to the Hawaii Institute of Geophysics. The new calibration values agree with those taken before the experiment up to 130°C ; the values above 130°C , while no longer linear (all components in the package were rated only to 125°C), were repeatable. Thus we believe that the $150 \pm 5^{\circ}\text{C}$ value obtained after 42 days in the hole is valid.

The discrepancy between predicted temperature at the bottom of the hole and the measured value can be explained if the hole acts as a conduit allowing hot water to rise from the more permeable basalt through the relatively impermeable sediments, forming a hot spring in the ocean bottom. The hole was probably heated over a period of time as hot water from below continued to enter the hole.

While there are other possible explanations for the temperature increase, we believe that the hot spring hypothesis is the most probable cause. Many authors have suggested that hydrothermal circulation is responsible for erratic heat flow values in the ocean³⁻⁹. Heat apparently is released in large amounts in regions where sediments are thin or where basement protrudes through the sediments⁵. In areas where sediments are thick, heat flow tends to be lower than expected because of the blanketing effect of the sediments. The theory of Parsons and Sclater¹⁰ predicts a value of 17 HFU for crust aged 0.5 Myr (hole 482-C) for conductive heat flow as compared with the measured value of 12 HFU, indicating that heat is being lost by means other than conduction even before the drilling. The drill hole is an efficient conduit whereby heat can flow through the low permeability sediments by convection. Recent discoveries of natural hot springs at ridge crests⁶ also document the importance of hydrothermal circulation in heat transfer near ridge crests and in the placement of hydrothermal ore deposits.

We thank Richard Hey and David Epp for helpful criticisms, and Rita Pujale for editorial assistance. This research was sponsored by NSF grant OCE 78-10772.

Fig. 1 The ocean sub-bottom seismometer. The sensor package was lowered to the bottom of the hole through the drill pipe by the Glomar Challenger. The pipe was then stripped from the wire and the recording package and anchor assembly attached and lowered to the ocean bottom.

An Acheulean industry with *Elephas recki* fauna from Namib IV, South West Africa (Namibia)

Myra Shackley

Department of Archaeology, University of Leicester, Leicester LE1 7RH, UK

Namib IV is located in the linear dune sea of the central Namib Desert (Fig. 1), where different generations of fossil calcrete have been exposed by sand shift in an interdune flat. Mid-Pleistocene faunal remains (including *Elphas recki*) were scattered over 62,500 m² of the valley floor, some bearing residual traces of red calcrete. The industry may be closely paralleled from certain East African sites (Olorgesailie¹, Kilombe², PDK and HEB 1/2 and 3, Olduvai Bed IV (ref. 3)), suggesting a date between 400 and 700 kyr BP. I show here that Namib IV provides the first dated evidence for the presence of Acheulean man in South West Africa, the earliest Pleistocene faunal remains from the Namib Desert and a *terminus post quem* for the ecological change from savannah to sand desert.

Randomly orientated artefacts were scattered on the present ground surface, the presence of residual calcrete patches on the ventral surface of some artefacts and bones suggesting that they

had recently been weathered from a formerly extensive calcrete deposit of which a few remnants are still visible. Preliminary reconnaissance of the total distribution area was completed in 1978, and a statistical analysis made of 394 artefacts found within one randomly-selected grid square (22,500 m²), together with the collection of all faunal material from the site. The implement assemblage included bifaces (handaxes and cleavers) comprising 30% of the total, the rest being spheroids (2%), chopper/cores (7%), small flake tools (58%), working debris, débitage and unretouched flakes. Raw materials were very varied, principally yellow, pink and grey quartzite with lesser quantities of dolomite, dolomitic marble and diamictite obtained from cobbles in the canyon of the Kuiseb river, some 8 km north of the site. Some relationship between raw material and artefact type was evidenced, for example, by the dolomite spheroids (bolas) and the large cleavers which were almost exclusively made of quartzite. Smaller flake tools and scrapers were made from quartz, obtained from veins in the local outcrops of mica-schist.

There was a marked tendency for the bifaces to be made on flakes, a frequent method of manufacture being the splitting of a large pebble and the trimming of a few flakes from one side only, leaving the other consisting almost entirely of cortex. This was particularly evident on the cleavers, where as few blows as possible had been used consistent with producing a serviceable edge of the required shape. The handaxes, which tended to be pick-like or chisel-ended variants of the 'classic' pointed handaxe, composed only 5% of the whole industry. The cleavers, representing a further 25% of the industry, were larger and heavier with a marked tendency to be made on side-struck flakes. All bifaces showed traces of heavy usage.

The manufacture of bifaces from large flakes is characteristic of the Acheulean and it has been suggested⁴ that the development of the technique may be crucial in differentiating Acheulean industries from Oldowan. Typologically although Namib IV may closely be paralleled by East African industries from

Fig. 1 Map of the central Namib Desert; inset shows its location in southern Africa.

Ologesailie, Kilombe and Olduvai IV, the thickness of the bifaces, low number of flake scars and lack of secondary working suggest that it might be slightly earlier in date, although firmly placed within the mid-Pleistocene Acheulean technocomplex. Certain features of the Namib IV assemblage, including the dominance of cleavers over handaxes, are in sharp contrast to the East African sites, although the complete absence of picks and the presence of sub-rectangular cores, spheroids and large number of flake tools reinforces the general similarity. Preliminary readings from Kilombe⁵ suggest that the site antedates the Brunhes-Matuyama transition, and is therefore >700,000 yr old. Isaac¹ has stated that it is likely that Ologesailie may date to before 400 kyr BP and it is suggested on typological grounds that Namib IV is of similar antiquity. The fauna included the mineralised remains of *Elphas recki*, together with one indeterminate alcelaphine antelope and one other medium-sized antelope. The *Elephas* remains fortunately included tooth fragments whose thin enamel, hypsodonty and tight enamel folding suggest that a late stage of *E. recki* is represented, probably comparable with Maglio's Stage 4 (ref. 6) as represented at Olduvai Bed IV, confirming the mid-Pleistocene date for the site.

The precise mode of formation of the calcrete deposit is as yet uncertain but it is undoubtedly connected with the former presence of surface water, probably a small ephemeral lake. The climatic shift which took place after the mid-Pleistocene resulted in an ecological change from savannah grassland with sufficient fodder for elephants to the present sand desert; a desiccation that resulted in a lowered water table and the formation of evaporites incorporating artefacts and bones lying on or near the former lake margins. The paucity of the bone refuse makes it impossible to say whether the artefact concentration represents a butchery site or a camp, but it is unlikely that hunters would have remained in the vicinity of their kills for more than a few days, due to competition from other, larger carnivores⁷. A butchery site visited on many occasions is the most likely hypothesis, an argument based on what Perkins and Daly⁸ called a 'schlepp effect', namely that bones which are bulky or of little nutritive value are unlikely to be removed from kill site to camp. Klein⁷ notes that the occurrence of elephant bones at Pleistocene base-camp sites in Africa is very rare, and that they are almost totally absent from the extensive faunas studied from South African cave sites. Acheulean butchery sites like Elandsfontein 'Cutting 10'⁷ are, conversely, often rich in elephant remains and sometimes, as in the case of Namib IV, these come from adult or sub-adult individuals.

Although the occurrence of Acheulean material in the Namib has been previously noted⁹ no associated fauna was preserved. It is hoped that an extension of the 1978 study of Namib IV will reveal typological and distribution information concerning the remains of the Acheulean in South West Africa, together with further details of the Pleistocene environment.

Fieldwork was financed by a grant from the Swan Fund (University of Oxford) and a Suzette Taylor Travelling Scholarship (Lady Margaret Hall, Oxford). I thank Richard Klein for identifying the fauna and the following for their assistance and permissions, Dr M. K. Seely, Mrs A. E. Smith-Partington, the staff of the Desert Ecological Research Unit (Gobabeb, Namibia) and the Division of Nature Conservation and Tourism, South West Africa.

In vitro flowering of embryoids derived from mature root callus of ginseng (*Panax ginseng*)

Wei-chin Chang & Yue-ie Hsing

Institute of Botany, Academia Sinica, Taipei, Taiwan, Republic of China

Seedlings of various crops pass through a juvenile phase during which they cannot be induced to flower¹. The delay in flowering caused by a long juvenile phase may last for years and is a major problem in breeding such crops. In field conditions, ginseng (*Panax ginseng* C. A. Meyer) usually flowers in the third year after germination², and breeding programmes have been hindered by the long time needed for genetic analysis. We report here a repeatable precocious flowering of embryoids derived from mature ginseng root callus cultured in a chemically defined medium. These embryoids produce flowers and fertile pollen without establishing normal seedlings.

In vitro somatic embryogenesis of ginseng was first reported by Butenko and her colleagues³, who found that spontaneous somatic embryogenesis occurred on cultured callus derived from various tissues, including leaf, petiole, anthophore and stem. However, attempts to regenerate whole ginseng plants from these embryoids failed. We have since reported conditions for such regeneration⁴.

Fig. 1 a, Cluster of embryoids derived from mature root callus ($\times 5$); b, a dicotyledonary embryoid ($\times 40$); c, flowers developed from an isolated embryoid ($\times 4$); d, a minuscule flower with well-developed anthers ($\times 10$); e, fertile pollen of well-developed flowers ($\times 500$).

Callus was obtained by aseptically culturing pith tissue of a mature ginseng root on an agar medium consisting of 2% sucrose, vitamins and the major and minor salts of Murashige and Skoog⁵. This basal medium (BM) supplemented with 2,4-dichlorophenoxyacetic acid (2,4-D, 5 mg l⁻¹) kinetin (2 mg l⁻¹). The cultures were kept in a growth chamber at 26 ± 1 °C in darkness. When subcultured, the callus grew most rapidly in BM plus 2,4-D (2 mg l⁻¹), kinetin (1 mg l⁻¹) N⁶-(Δ²-isopentenyl)-adenine (2iP, 1 mg l⁻¹). Embryoids were obtained by reducing the 2,4-D to 1 mg l⁻¹ and omitting kinetin and 2iP (Fig. 1a, b). They failed to develop and remained 2–3 mm long. Some of them, however, gave rise to a mass of friable callus, which produced more embryoids when subcultured on BM plus gibberellic acid (GA), adenine sulphate, tyrosine and charcoal; the optimal combination of these factors was 0.1 mg l⁻¹, 40 mg l⁻¹, 50 mg l⁻¹ and 0.5% respectively. Such embryoids, however, failed to develop further in subculture.

To obtain further development, embryoids 2–3 mm long were isolated from the callus and subcultured either on half-strength BM supplemented with benzyladenine (BA, 1 mg l⁻¹) and GA (0.5–1 mg l⁻¹) or B5 medium⁶ supplemented with BA (1 mg l⁻¹) and GA⁷ (1 mg l⁻¹). Well-structured flowers were repeatedly observed when the embryoids were cultured on the supplemented B5 medium at 26 ± 1 °C under a 16:8 light-dark regime, 1,500 lux (Fig. 1c). Two cotyledons of the cultured embryoid developed into a mass of green unorganised tissue, and the apical meristem located between two cotyledons transformed

into a peduncle terminated by a simple umbel with 3 to 15 flowers. These flowers were small, about 2–3 mm across. Each flower consisted of five-toothed green calyx, five yellowish green entire petals, 5 to 10 short stamens with oblong anthers, and two green pistils. These well-structured floral parts were minuscule but easily recognisable (Fig. 1d). About 90% of the pollen grains (Fig. 1e) were fertile as revealed by smearing and differential staining by Alexander's procedure⁷.

Thus embryoids have the potential to produce flowers directly in defined conditions. Compared with the intact plant systems used in studies of flowering, these embryoids have the advantage that many of them can be obtained in defined sterilised culture⁴, and within 1 month of subculture, as described here, flowers can be obtained. Thus the embryoid system could provide experimental material for studies of flowering without the need for the normal ginseng juvenile phase (3 yr).

We thank Miss Chan-wong Huang for technical assistance. This work was supported by National Science Council, Republic of China.

Luteinising hormone-releasing and anti-fertility properties of a glucagon-selective somatostatin analogue

Frederick J. Bex*, Alan Corbin†, Dimitri Sarantakis‡ & Eric Lien§

Sections of Endocrinology†, Medicinal Chemistry‡, and Biochemistry§, Wyeth Laboratories, Inc., Box 8299, Philadelphia, Pennsylvania 19101

The hypothalamic tetradecapeptide, somatostatin (SRIF), inhibits the secretion of growth hormone (GH)¹ and numerous other hormones², including insulin and glucagon^{3,4}. Attempts to use SRIF as an adjunct in the treatment of diabetes mellitus^{5,6} met with limited success due to its short biological half-life^{7,8} and the undesirable diabetogenic activity of its insulin-lowering properties^{3,9,10}. Efforts at synthesis have yielded SRIF derivatives with prolonged GH-lowering activity which did not suppress glucagon or had equivalent insulin-inhibiting activity^{11–14} as well as several short-acting compounds with the appropriate glucagon specificity^{15,16}. A dodecapeptide analogue [des-Ala¹, Gly²] His^{4,5}-D-Trp³-SRIF (Wy-41, 747) has been identified that combines selective inhibition of GH and glucagon release with prolonged activity^{17,18}. However, in routine pharmacological tests chronic treatment of mature rats with Wy-41, 747 produced anti-reproductive effects resembling those described for luteinising hormone (LH)-releasing hormone (RH) and its agonists^{19–25}. We report here that Wy-41, 747, unlike SRIF and other of its analogues tested, releases LH, induces ovulation and inhibits pregnancy when administered before or after implantation; these properties are traditionally associated with the separate LH-releasing class of peptides.

Wy-41, 747 was administered to ten adult male and ten adult female (initiated on metoestrus of 4-d cycle) rats at a total dose of 900 µg per kg, given subcutaneously in three equally divided injections at 0900 h, 1500 h and at 0900 h on the following day.

A further group of ten males received SRIF in a total dose of 4.3 mg per kg, in view of its lesser potency and shorter half-life, delivered as six divided doses at 0900 h, 1000 h, 1500 h, 1600 h and 0900 h and 1000 h on the following day. Animals injected with vehicle (0.9% saline adjusted to pH 4.0 with HCl) served as controls. One hour after the final injection, serum was collected for radioimmunoassay of reproductive hormones^{21,26}. Wy-41, 747 caused a 2.9-fold increase in LH in males (control, 70 ± 15 ng ml⁻¹; Wy-41, 747, 203 ± 27 ng ml⁻¹) and a 21.9-fold increase in females (control 21 ± 4 ng ml⁻¹; Wy-41, 747, 466 ± 80 ng ml⁻¹). SRIF released no LH in males. Serum prolactin levels were reduced, although not significantly, by Wy-41, 747 in both sexes. The analogue depressed testosterone significantly in males ($P < 0.05$) but had no effect on oestradiol and progesterone in females. Thus Wy-41, 747, unlike its parent molecule SRIF^{2,27,28}, can release LH effectively and may also inhibit the release of prolactin as well as gonadal steroidogenesis.

Confirmation of the LH-releasing properties of Wy-41, 747 was provided by its ability to induce ovulation. At 1330 h on the day of proestrus, pentobarbital (50 mg per kg) was injected intraperitoneally to inhibit the spontaneous surge of LH necessary for ovulation. Test compounds were administered subcutaneously in saline, pH 4.0, between 1340 h and 1350 h and LH-releasing activity was determined by the presence of oviducal eggs the next morning (oestrus). LHRH was included as a standard by which to compare Wy-41, 747 and SRIF. As Fig. 1 shows, Wy-41, 747, unlike SRIF, induced ovulation in a dose-related fashion. Although very effective in this test, Wy-41, 747 was only 1/10 as potent as the endogenous LH-releasing peptide, LHRH. Preliminary evaluations of the ovulation-inducing activity for several other SRIF analogues indicate that the LH-releasing property is unique to Wy-41, 747.

A further group of pentobarbital-blocked proestrous rats was injected with the ED₁₀₀ dose of Wy-41, 747 necessary for ovulation (100 µg) and blood samples were taken by heart puncture 1 and 2 h later. Within 1 h the LH of the seven analogue-treated animals had increased to a level 6.6 times as great as that in three rats receiving saline; after 2 h the difference was 25.8 times. Wy-41, 747 also inhibited serum prolactin at both intervals after injection (1 h: saline control, 80 ± 37 ng ml⁻¹; Wy-41, 747, 19 ± 8 ng ml⁻¹; 2 h: saline control, 82 ± 32 ng ml⁻¹; Wy-41, 747, 11 ± 5 ng ml⁻¹).

LHRH and its agonistic analogues, in spite of their fertility-enhancing classification (LH release, ovulation induction), consistently produce anti-fertility effects, including that of inhibiting pregnancy^{19,20}. Because this is presumed to be mediated by inappropriately increased endogenous LH levels^{21,22}, Wy-41,747, which possesses the LH-releasing property, was tested for its effect on pregnancy in rats. Beginning on day 1 of pregnancy (appearance of vaginal sperm) and continuing to day 7 (pre-implantational period), or beginning on day 7 and continuing to day 12 (post-implantational period), all compounds except SRIF were administered in a divided daily dose at 0900 h and at 1500 h. SRIF, because of its limited duration of activity, was administered in four divided daily doses at 0900 h, 1000 h, 1500 h and 1600 h. Autopsy and assessment of pregnancy status (the presence of at least one normal fetus was the criterion for pregnancy) occurred on day 14 (pre-implantation groups) or day 18 (post-implantation groups). Figure 2 shows that Wy-41,747 can terminate pregnancy when administered during either days 1–7 or days 7–12; in both tests it was approximately one-half as potent as LHRH. SRIF had little (pre-implantation) or no (post-implantation) inhibitory effect at high doses.

Fig. 1 Effect of LHRH (○), Wy-41,747 (●), and SRIF (×) on the induction of ovulation in pentobarbital-blocked proestrous rats. Numbers of rats are given in parentheses.

These results demonstrate that Wy-41,747, in contrast to SRIF and certain other SRIF analogues, has a reproductive pharmacological profile remarkably similar to that of LHRH. This SRIF derivative can release LH, induce ovulation and inhibit pregnancy before and after implantation, all integral properties of LHRH and LHRH agonists. Thus, the structural modifications of SRIF resulting in Wy-41,747 have resulted in a unique molecule with the high potency and the long-acting selectivity of the parent molecule (that is, ability to lower GH and glucagon) combined with characteristics of a separate class of peptides.

The anti-fertility effects of chronic administration of Wy-41,747, in addition to inhibition of pregnancy, include: in the male, decreased testicular and sex accessory weights, histological evidence of disorganised seminiferous tubules, inhibition of spermatogenesis; and, in the female, reduced folliculogenesis and uterine atrophy. These effects are strikingly similar to those reported for LHRH and its agonistic analogues^{21–25}. It has been proposed that the anti-reproductive action of LHRH/LHRH agonists occurs, in part, through an excessive release of LH, thereby reducing gonadal LH receptors (down-regulation) which is probably exacerbated by an associated decline in serum

Fig. 2 Post-coital effect of LHRH (○), Wy-41,747 (●), and SRIF (×) in the rat. *a*, Inhibition of pregnancy as determined on day 14 after treatment during the days 1–7, pre-implantation; effect was characterised by lack of uterine implantation sites or resorbing sites. *b*, Inhibition of pregnancy as determined on day 18 after treatment during days 7–12, post-implantation; effect was characterised by resorbing sites and/or placental scars. Numbers of rats are given in parentheses.

prolactin levels^{21,22}. This, in turn, results in depressed gonadal steroidogenesis and a disruption of gonadal steroid-dependent tissues. The ability of Wy-41,747 to release LH and lower prolactin suggests that its anti-reproductive activity may occur through a similar pituitary-mediated downregulatory mechanism, although, as recently identified for LHRH and an LHRH agonist^{29,30}, direct gonadal effects may be involved as well.

We thank Dr G. Niswender for progesterone antiserum (GDN-337), Dr G. Abraham for testosterone antiserum (S-1599-3), and the NIAMDD Pituitary Hormone Distribution program for rat LH and prolactin radioimmunoassay kits.

Proposed mechanism of cholinergic action in smooth muscle

D. Michael Salmon* & Thomas W. Honeyman

Departments of Biochemistry and Physiology,
University of Massachusetts Medical School, 55 Lake Avenue North,
Worcester, Massachusetts 01605

An increased turnover of phosphatidate and phosphatidyl inositol has been found in many tissues where hormones or neurotransmitters are postulated to raise Ca^{2+} influx¹, for example in smooth muscle²⁻⁴. However, the relationship between changes in phospholipid metabolism and changes in Ca^{2+} permeability was unknown. Following recent reports on the interactions of Ca^{2+} with phosphatidic acid in membranes and artificial systems, we investigated the hypothesis that phosphatidate accumulation mediates the action of cholinergic and other stimuli on Ca^{2+} influx. We report here that synthesis and accumulation of phosphatidate was accelerated in smooth muscle cells stimulated by carbamylcholine with a similar time course to that of contraction. This alteration in phosphatidate metabolism does not seem to result from an increase in intracellular Ca^{2+} or depolarisation of the cell membrane. Furthermore, submicromolar concentrations of phosphatidate rapidly produce contractions of isolated smooth muscle cells. These results support the contention that cholinergic-induced changes in membrane Ca^{2+} permeability in smooth muscle could be mediated by phosphatidate accumulation.

Several predictions of this hypothesis were evaluated. First, cholinergic stimulation should increase phosphatidate accumulation. Second, phosphatidate accumulation should occur independently of, and at least as rapidly as, the change in Ca^{2+} movement. Finally, exogenous phosphatidate should produce effects similar to those elicited by cholinergic stimulation. The use of enzymatically disaggregated smooth muscle cells from the stomach muscle of *Bufo marinus*⁵ afforded exceptional advantages in testing these predictions. The muscarinic response of those cells has been well studied⁶. Furthermore, changes in Ca^{2+} movements can be inferred from changes in the contractile state of the isolated cell, and their use obviates interpretive complications inherent to studies with intact tissues: heterogeneous cell populations, multiple diffusion barriers, and intercellular coupling⁷.

Changes in phosphatidate accumulation were assessed by following the incorporation of ^{32}P into the phospholipid. Within 10 s (a time when contraction is not yet maximal) after exposure to carbamylcholine, ^{32}P incorporation into phosphatidate was increased nearly threefold (Fig. 1). Similarly, brief periods of exposure to carbamylcholine increased phosphatidate content (assayed as glycerol-1-phosphate after saponification) from 340 to 570 pmol per aliquot cell suspension ($\sim 10^6$ cells). These data demonstrate that cholinergic stimulation increases phosphatidate accumulation, and this accumulation occurs rapidly enough to mediate changes in Ca^{2+} movement.

To assess whether the increased ^{32}P -phosphatidate labelling was independent of the increases in intracellular Ca^{2+} and/or the membrane depolarisation produced by cholinergic stimulation, the effects of K^+ on phosphatidate were studied. Exposure to high concentrations of K^+ produces contraction⁶ and would also be expected to depolarise the membrane. However, as K^+ failed to affect ^{32}P incorporation into phosphatidate, the effect of carbamylcholine on phosphatidate seems to be independent of membrane depolarisation and increased Ca^{2+} levels.

These studies are consistent with the hypothesis that increased phosphatidate accumulation may mediate the

Fig. 1 Time course for the effect of carbamylcholine (carbachol) and KCl on ^{32}P incorporation into phosphatidate in isolated smooth muscle cells. For comparison the time course of carbachol-induced contraction is shown (data replotted from Fay and Singer⁶). Suspensions of isolated smooth muscle cells were incubated for 15 to 30 min in amphibian Krebs-Ringer bicarbonate buffer containing ^{32}P ($10\text{--}20\ \mu\text{Ci ml}^{-1}$) before exposure to carbachol (10^{-4}M) or KCl (40 mM) for the times indicated. The cells were disrupted by sonication (Branson cell disruptor) in the presence of 5% trichloroacetic acid and ^{32}P labelled phospholipids were isolated by two-dimensional thin layer chromatography on silica gel 60 (Merk) using solvent systems described by Abdel-Latif *et al.*¹⁸ ^{32}P -phosphatidate content was calculated from the specific activity of ^{32}P in the incubation medium. To correct for differences in cell density between experiments the increase in ^{32}P -phosphatidate produced by carbachol or KCl was expressed as a per cent change relative to ^{32}P -phosphatidate in unstimulated cells. Values for ^{32}P -phosphatidate of unstimulated cells ranged between 0.27 and 2.3 pg atoms per aliquot cell suspension. Note that carbachol increased ^{32}P -phosphatidate accumulation nearly threefold within 10 s (mean and standard error calculated from four experiments), a time where contraction is not yet maximal. Exposure of cells to KCl, which also causes contraction with a time course similar to that produced by carbachol, failed to increase ^{32}P -phosphatidate accumulation. Change in ^{32}P -phosphatidate: ○, carbachol; ● KCl; × contraction of carbachol.

increased Ca^{2+} levels produced by cholinergic stimulation. If this is so, then phosphatidate added exogenously should produce an increase in intracellular Ca^{2+} levels, hence contraction. Previous reports have shown that phosphatidate can elicit contractions in intact smooth muscle strips⁸, but such studies cannot rule out an indirect action (such as release of endogenous neurotransmitters). In isolated smooth muscle cells, phosphatidate at concentrations as low as 10^{-8}M produced contractions within 10 s. These contractions were equal in magnitude to those produced by carbamylcholine (Fig. 2).

As phosphatidate lies at an important branch point in glycerolipid metabolism, the ^{32}P labelling of phosphatidyl inositol noted by many investigators in other systems¹ may also arise as a consequence of increased ^{32}P -phosphatidate accumulation. The finding that carbamylcholine stimulates ^{32}P incorporation into phosphatidyl inositol in isolated smooth muscle cells subsequent to accumulation of ^{32}P -phosphatidate supports this contention⁴. It has previously been suggested that an increase in phosphatidyl inositol breakdown leading to an opening of 'Ca²⁺ gates' is the mechanism by which Ca^{2+} influx is accelerated by several

agents^{1,9,10}. Although the present studies provide no information concerning the events leading to increased phosphatidate accumulation in response to carbamylcholine, it is likely that an accelerated hydrolysis of phospholipids, possibly including phosphatidyl inositol¹¹, is involved. However, the present studies define the time during which these events occur.

The way in which phosphatidate accumulation may initiate an increase in Ca^{2+} influx in the contractile response of smooth muscle to cholinergic agents can be inferred from other studies. As phosphatidate is an ionophore in artificial systems¹² it is reasonable to postulate a similar role in the cell membrane. The finding that phosphatidate monolayers are collapsed in the presence of Ca^{2+} , in effect removing the Ca^{2+} -phosphatidate complex from the interface, suggests the possibility that Ca^{2+} traverses the membrane complexed with phosphatidate, perhaps in the form of inverted micelles¹³. Furthermore, the accumulation of phosphatidate could increase membrane Ca^{2+} permeability without necessarily altering Na^+ or K^+ permeability since the affinity of phosphatidate for Ca^{2+} in aqueous media is 10^5 greater than that for monovalent cations¹⁴. Finally, if phosphatidate acts physiologically as an ionophore, then, to provide specificity in the control of membrane permeability, it would be expected to be ordered and segregated in regions of the membrane distinct from the bulk of zwitterionic phospholipids forming the bilayer. Numerous reports support the concept that phosphatidate forms electronegative domains, particles, or inverted micelles in membranes, especially in the presence of Ca^{2+} and basic proteins¹⁵⁻¹⁷. Thus, the association between changes in Ca^{2+} influx and changes in phosphatidate metabolism, noted in smooth muscle and many other tissues in

response to cholinergic and many other stimuli may be explained primarily by the generation of phosphatidate domains, functioning as Ca^{2+} 'channels'.

Is phosphatidic acid a calcium ionophore under neurohumoral control?

James W. Putney Jr*, Stuart J. Weiss, Cynthia M. Van De Walle & Raymond A. Haddas

Department of Pharmacology, Wayne State University, School of Medicine, 540 E. Canfield Avenue, Detroit, Michigan 48201

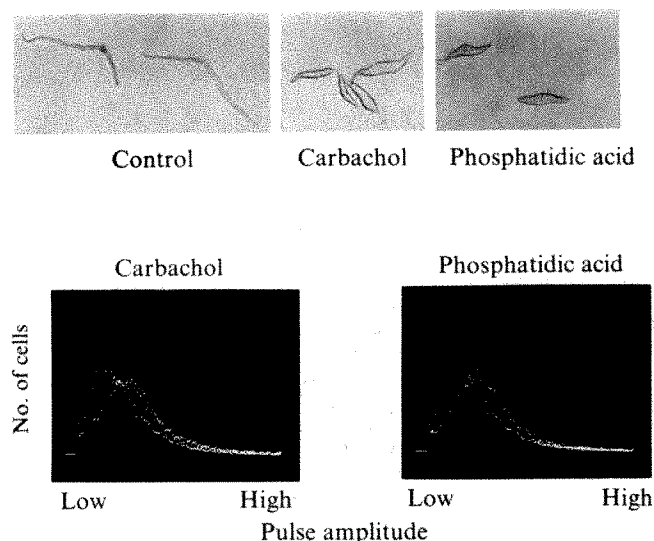

Fig. 2 Effects of exogenous phosphatidate on contractile state of isolated smooth muscle cells. Aliquots of single cell suspensions were exposed to 10^{-4} M carbamylcholine (carbachol) or 10^{-6} M phosphatidic acid (Sigma, grade I) for 15 s before fixation with acrolein⁵. Photomicrographs were taken at $\times 360$. The lower panel shows the pulse amplitude histograms obtained from 10^4 cells when aliquots of these same cell suspensions were analysed with a Coulter counter according to the method of Singer and Fay⁵. Note that both carbachol and phosphatidate produced contraction of the isolated cells such that cells length decreased by 60-70%. Phosphatidate-induced contraction was also noted when contractile state was assessed by Coulter counter analysis. Note that the pulse amplitude histogram generated by cells exposed to carbachol is shifted towards larger amplitude pulses when compared to the histogram generated by unstimulated cells. This increase in the number of large amplitude pulses is indicative of contraction of the isolated cells. A similar shift in the pulse amplitude histogram is noted for cells exposed to phosphatidate. In this experiment both carbachol and phosphatidate produced a 20% increase in the number of large amplitude pulses. In other experiments exposure of cells to phosphatidate at concentrations as low as 10^{-8} M or for as little as 5 s produced contractions of isolated smooth muscle cells.

There has recently been renewed interest in a previously observed phenomenon¹ whereby hormones and neurotransmitters alter the rate of incorporation of ^{32}P -phosphate into phospholipids, specifically, phosphatidylinositol (PI) and phosphatidic acid (PA)². This has arisen from a theory formulated by Michell and coworkers which postulates that this 'phospholipid effect' is in some way intimately involved in the mechanism by which certain neurotransmitters and hormones activate membrane Ca gates²⁻⁵. However, although Michell's observations are consistent with a phospholipid involvement probably somewhere between receptor occupation and Ca gating, they do not suggest what the specific role of the phospholipids in the Ca gating mechanism might be. Recently, Salmon and Honeyman suggested⁶ that the critical event may be the net formation of PA following the net breakdown of PI which occurs in pancreas⁷, platelets⁸ and smooth muscle^{6,9}. PA has been shown to behave as a Ca ionophore in a Pressman chamber¹⁰, and thus it is possible that an increase in PA concentration in cellular membranes might increase the Ca permeability of those membranes (see also ref. 5). In the rat parotid, receptors associated with Ca gating (muscarinic, α -adrenergic and substance P) show a phospholipid effect whereas β -adrenergic receptors (which act on adenylate cyclase) do not^{11,12}. The phospholipid effect is Ca independent, and is not produced by the divalent cationophore A23187 (refs 11, 12). Also, an easily quantifiable response of this tissue (K efflux measured as release of ^{86}Rb) is absolutely dependent on the concentration of external Ca (ref. 13) and, by inference, on the magnitude of Ca influx¹⁴. We report here evidence suggesting that PA, which is formed during the reaction sequence of the phospholipid effect, may directly mediate the inward movement of Ca that results from activation of surface membrane receptors.

Levels of PA were measured in dispersed parotid cells¹⁵ with two-dimensional TLC¹⁶. Unstimulated cells were found to contain 1.24 ± 0.15 nmol per mg protein PA ($n=6$). This was significantly ($P<0.005$) increased to 2.83 ± 0.37 nmol per mg

Fig. 1 Activity of phosphatidic acid (PA) in stimulating Ca-dependent ^{86}Rb release from rat parotid gland slices. The protocol of loading tissues with ^{86}Rb has been described elsewhere^{13,18}. The Ringer medium also contained 10^{-5} M atropine and 10^{-4} M phentolamine to prevent effects of endogenous neurotransmitter release on ^{86}Rb efflux. The Mg^{2+} concentration of this medium, and that for the experiments shown in Fig. 3, was 1.2 mM. This amount of Mg, about one-tenth of the K_a for Mg^{2+} , is not sufficient to interfere appreciably with Ca transport, but is necessary in the biological experiments to prevent membrane 'leakiness' that can occur on omission of extracellular Ca (ref. 22). Initially, the Ringer contained no added Ca and 10^{-4} M EGTA. At $t = 20$ min, phosphatidic acid was added to the media in the concentrations indicated, and at $t = 24$ min, CaCl_2 was added to a final concentration of 10 mM. Concentrations of PA (final) were: \times , none (control); \bullet , 10^{-6} M; \circ , 10^{-5} M; \blacktriangle , 10^{-4} M; \triangle , 10^{-3} M. The PA used was chromatographically pure ($\geq 99\%$), synthetic material (dipalmitoyl L- α -phosphatidate Na, Sigma P-4013). The values are means of three experiments each. The standard error averaged less than 10% of the means. Inset, basal ^{86}Rb efflux was subtracted and net increases in ^{86}Rb efflux at each concentration were calculated. Means of three experiments ± 1 s.e.m.

Fig. 2 Inhibition of PA-mediated ^{45}Ca transport into CHCl_3 by various agents. Equilibrium partitioning of ^{45}Ca (10^{-5} M) from 1.0 ml of Ringer medium (without Mg^{2+}) containing 10^{-4} M PA into 5.0 ml CHCl_3 was determined in the presence and absence of several agents at the concentrations indicated. The data are expressed as % inhibition; that is, 100% means no radioactivity in the CHCl_3 . The agents used were: \square , La^{3+} ; \blacksquare , Tm^{3+} ; \circ , neomycin; \bullet , Co^{2+} ; \blacktriangle , Ni^{2+} ; \times , Ca^{2+} ; \triangle , Mg^{2+} . The data summarise three separate experiments, each assayed in triplicate. The standard errors averaged 5% of the means.

protein PA ($n = 8$) on 30 min incubation with the muscarinic agonist, methacholine (10^{-4} M). Continued muscarinic receptor activation for this period of time produces a sustained activation of surface membrane Ca gates¹⁷.

Figure 1 shows the Ca-dependent stimulation of ^{86}Rb release from parotid gland slices by various concentrations of PA. Phosphatidylinositol and phosphatidylserine (another acidic phospholipid) had no effect at 10^{-4} M concentrations. Because the PA did not stimulate ^{86}Rb release until Ca was present, nonspecific effects on membrane permeability or an ability to transport ^{86}Rb directly can probably be ruled out. Also, as can be seen in Fig. 1, PA did not cause a transient response before the addition of Ca, as is typical for agents acting on endogenous receptors¹⁸. We conclude, therefore, that the action of exogenous PA is probably not mediated through endogenous receptors.

Fig. 3 Concentration-effect relationship for Ca-dependent ^{86}Rb release. The data were obtained from experiments similar in design to those shown in Fig. 1, except that the receptor-controlled Ca gating mechanism was activated with the muscarinic agonist, carbachol. To assure that Ca gating was rate limiting, a submaximal concentration of carbachol (10^{-6} M) was used¹⁸. Basal rates of ^{86}Rb release (before Ca was added) were subtracted. The linear portions of the curves were fitted by least-squares analysis, and the log-displacement of the curves at $y = 3\% \text{ min}^{-1}$ was used to calculate K_a values. \times , Control ($n = 4$); \bullet , plus 2 mM Co^{2+} ($n = 3$). The dispersions represent s.e.m.s. Other agents were tested with similar procedures and three or four replications each.

The assay of ^{45}Ca partitioning into CHCl_3 due to PA was carried out as follows: 1.0 ml of Ringer medium (with no Mg) containing 10^{-5} M ^{45}Ca and 10^{-4} M PA was shaken with 5.0 ml of CHCl_3 . After sufficient time for the system to come to equilibrium, the radioactivity in the organic phase was determined. In the absence of PA, virtually no radioactivity was detectable in the organic phase. With PA present, about 5% of the radioactivity originally added was extracted by the CHCl_3 . This effect was comparable to that seen with 20 μM A23187. Phosphatidylinositol and phosphatidylserine did not augment ^{45}Ca partitioning into CHCl_3 . Tyson *et al.*¹⁰ surveyed several phospholipids and found that only phosphatidic acid and cardiolipin produced this effect. The abilities of various agents to inhibit this process were determined by repeating the extraction in the presence of various concentrations of the appropriate reagents. The results are shown in Fig. 2. The relative potencies of the agents tested were in the order: $\text{La}^{3+} > \text{Tm}^{3+} > \text{neomycin} > \text{Co}^{2+} > \text{Ni}^{2+} \approx \text{Ca}^{2+} \gg \text{Mg}^{2+}$. Although the actual mechanism involved in the PA-induced partitioning of ^{45}Ca into

Fig. 4 Relationship between inhibition of ^{45}Ca -partitioning activity of PA and inhibition of receptor-activated Ca-dependent ^{86}Rb release by various agents. The ordinate values are concentrations of agent necessary to inhibit ^{45}Ca transport by PA into CHCl_3 by 50% as determined graphically from the data in Fig. 2. The abscissae are apparent dissociation constants (K_d) for antagonism of Ca gating in parotid slices determined as illustrated for Fig. 3. The agents were: \square , La^{3+} ; \blacksquare , Tm^{3+} ; \circ , neomycin; \bullet , Co^{2+} ; \blacktriangle , Ni^{2+} ; \triangle , Mg^{2+} ; \times , Ca^{2+} (K as agonist estimated). The line was fitted by least-squares analysis. Ca was omitted, however, because the K value, as an agonist, is somewhat uncertain. The slope (using logarithms) was 0.998 and the correlation coefficient was 0.993.

CHCl_3 is not known, it is reasonable to conclude that the potencies of these inhibitory cations in preventing this process reflects their ability to compete with ^{45}Ca for binding to the negatively charged head group of the PA. In addition, the Ca antagonist D-600, as well as procaine and tetracaine, were tested (not shown) and found to be somewhat less potent than Mg^{2+} .

The same agents were tested for their ability to inhibit endogenous, receptor-controlled Ca gating. The protocol here was to determine the Ca concentration-effect relationship for stimulating ^{86}Rb release (with carbachol as agonist) in the presence and absence of a fixed concentration of antagonist, and then to calculate antagonist dissociation constants from the shift in the Ca concentration-effect curve¹⁹. An example is shown in Fig. 3. The potencies for inhibition of Ca-mediated ^{86}Rb release (in the case of Ca, its apparent K value as agonist) ranked as $\text{La}^{3+} > \text{Tm}^{3+} > \text{neomycin} > \text{Co}^{2+} > \text{Ni}^{2+} > \text{Ca}^{2+} > \text{Mg}^{2+}$. Procaine, tetracaine and D-600 had no antagonistic activity below 10^{-3} M, and at higher concentrations produce inhibition by other mechanisms^{20,21}.

The correlation between inhibition of partitioning activity of PA and apparent affinity for the Ca influx mechanism (as assayed by ^{86}Rb release) is illustrated in Fig. 4. Taken with the observations that receptor activation increases the PA content of the parotid, and that exogenous PA can stimulate a Ca-dependent response in the parotid, these data suggest that PA may function in the physiological mechanism for Ca gating. This does not imply that PA must act in as simple a manner as for the ionophores in general; auxiliary structures and functional groups may also be involved. In red cells, for example, increased levels of PA do not apparently lead to augmentation of Ca influx⁵. As the red cell does not seem to have any Ca-gating mechanism under receptor control, this may indicate that other structures necessary for this phenomenon are also absent. However, in the parotid gland and other tissues, receptor mechanisms are present which regulate Ca gating as well as the membrane concentration of PA. On the basis of the data presented here, we suggest that the critical binding site for Ca

gating in these tissues could well be receptor-regulated phosphatidic acid.

These studies were supported by NIH grants DE-04067 and GM-07176. We thank R. Quinones and L. Hunt for technical assistance, and Dr T. Honeyman for helpful suggestions and for supplying us with a preprint of his manuscript⁶.

Motoneurone counts in *Xenopus* frogs reared with one bilaterally-innervated hindlimb

Alan H. Lamb

Department of Pathology, University of Western Australia, Perth, Australia

The death of large numbers of young neurones is a striking feature in the developing nervous system. Many authors have postulated that the neurones are produced in excess of the numbers that their target tissues can support, forcing them to compete for survival¹⁻³. Observations on developing limb motoneurones (ventral horn cells) in both frogs and chicks seem to support this hypothesis. Normally, one-half to three-quarters of ventral horn cells die as limb movements begin^{4,5}, but some of these (up to 25% in chicks, 7% in frogs) can be rescued by the provision of supernumerary limb buds before motor axon outgrowth begins⁶⁻¹⁰. Conversely, amputation of the limb bud causes an increased death rate approaching 100% (refs 4, 11). The crucial test of the hypothesis depends on its prediction that the limb should limit the number of surviving motoneurones, and here I have attempted to make the test. For this, both sides of the spinal cord were forced to project to a single hind limb bud well before the onset of ventral horn cell death. It was found that the combined total of surviving motoneurones (right plus left sides) projecting to the single limb exceeded the number that projects to one limb in normal animals by up to ~100%. It is concluded that the limb does not limit the number of survivors, and therefore the hypothesis is refuted, at least for ventral horn cells. It now seems more likely that motoneurone numbers are determined either by the need to eliminate ventral horn cells not connected with appropriate limb regions, or by factors operating within the central nervous system.

Fig. 1 *a*, Stage 49 tadpole (ventral view) after operation to move one limb bud (black arrow) into the midline. The other limb bud was first removed together with a small margin of surrounding epithelium. An incision was made through the tail fin caudal and dorsal to the anus and extended into the trunk along the dorsal surface of the peritoneal cavity, stopping just short of the renal duct. The flap of tail fin containing the anus (white arrow) was pulled across and fixed against the body wall with a fibrin clot to pull the remaining limb bud into the midline against the retroperitoneal wound. The flap returned to its normal position after 1 or 2 days, leaving the limb bud adhering to the new position. $\times 11$. *b*, Juvenile frog (M146) with a midline limb (ventral view). Photograph taken after fixation. This was the only experimental animal to have an abnormal limb, with two missing toes and a slightly reduced range of movement at the hip. $\times 2$. *c*, Juvenile frog (M213) without limb bud displacement (dorsal view). After amputating the other limb bud, a needle was used to tear the retroperitoneal region separating the two limb buds. Among the natural barriers to axon growth in this region are some large blood vessels which caused heavy bleeding. However, blood flow through nearby structures including the remaining limb seemed unaffected. $\times 7$. All operations were carried out in a solution containing 1 g sea salt, 4 g NaCl and 9 g l⁻¹ D-glucose plus 1 : 5,000 MS222. Tadpoles recovered in a solution containing 5 g l⁻¹ NaCl.

Operations were performed on 10–15-day-old *Xenopus laevis* tadpoles at stages 49 and 50 (ref. 12), when motor axon invasion of the limb buds is about to begin¹³. (Degeneration of ventral horn cells begins about a week later at stage 53, lasts 3–5 weeks until stage 60 and causes the loss of about 75% of the original population.) After removing one limb bud, the other was either left *in situ* or displaced into the midline, dorsal to the anus (Fig. 1*a*). Midline barriers which normally confine the spinal nerves to their own sides were disrupted with a needle. Only eight tadpoles survived the operations but they matured without delay. Limb buds regenerated in three tadpoles and were removed as they appeared.

In all except one frog with minor abnormalities (M146, Fig. 1*b*), the single hind limbs were normal in every respect including muscle bulk and amount and character of visually observable movements. None of the frogs had any trace of a limb, pelvic bones or muscles on the amputated side. To prove that in the metamorphosed frogs the limb was innervated by both sides of the cord, motoneurons projecting to the limb were labelled by retrograde axonal transport of horseradish peroxidase (HRP) either injected into the gastrocnemius muscle or applied to the proximal stump of the sciatic nerve after transection in the thigh¹⁴ (Fig. 2*a*). Further evidence of bilateral innervation was obtained at dissection 2 days later (7–14 days after completion of metamorphosis) by observing the spinal nerves from both sides entering the limb (Fig. 2*b*). The dorsal root ganglia were not preserved for cell counts but they seemed normal in size at dissection.

The numbers of motoneurons ipsilateral to the remaining limb were normal in all animals (Table 1). Contralateral motoneuron numbers varied from 11 to 94% of normal. Summing the two sides gives the total number of motoneurons projecting to the single limbs. In the cases with good bilateral innervation (over one-third contributed by the contralateral side) the totals ranged from 2,325 to 3,189, far exceeding the number of motoneurons projecting to one limb in control animals (range 927–1,704, Table 1). This result shows that the

Table 1

Frogs M65–69, M146 and M160–213 were reared from three different batches of tadpoles of different parentage. Unoperated controls were raised in the same tank as M187 and M188. Sham-operated controls had midline barriers disrupted but no limb bud amputation. In two of these cases a few motoneurons were found to project contralaterally (2 and 16 contralateral HRP-labelled cells; one gastrocnemius injected). 'Other operated' controls had partial deletions of one limb bud at stage 50, but no disruption of midline barriers. Counts are from the unoperated sides.

* Limb bud displaced into the midline.

† Regenerating limb bud removed. All regenerates were less than 0.3 mm long on removal.

limb does not limit the number of motoneurons projecting to it at projection densities found in normal animals. It also seems unlikely that there is a limit at the higher densities achieved in this experiment. This is shown by the absence of any correlation between the proportion of the total (ipsilateral plus contralateral) motoneurone projection contributed by the contralateral side, and the ipsilateral motoneurone counts ($r = -0.073$).

Fig. 2 Evidence for bilateral innervation. *a*, Transverse section of frog (M69) spinal cord showing HRP labelled motoneurons in both ventral horns. Bilateral labelling was also found in all other experimental animals except M146, which was not given HRP. In the case illustrated here, 30% HRP (Sigma VI) was applied to the transected sciatic nerve in the thigh. As in normal animals¹⁴, this method leaves about half the motoneurons unlabelled. Presumably, they project to the limb by other nerve trunks, or leave the sciatic nerve proximal to the transection. $\times 70$. *b*, Spinal nerves from both sides of the vertebral column (V) of M188 join to form one nerve trunk (arrow) before entering the base of the limb (L). $\times 14$. Spinal cords were dissected out and prepared for HRP histochemistry and cell counting by fixation in cold phosphate-buffered (pH 7.0) 2% glutaraldehyde for 4 h followed by overnight washing in running water. Cords were then immersed in 0.08% buffered diaminobenzidine tetrahydrochloride (Sigma) to which H_2O_2 had been added, after 1 h, to a concentration of 0.01%. Incubation at room temperature continued for 45 min before standard paraffin embedding for serial sections. Sections were mounted unstained in DPX and viewed by phase contrast microscopy. Counts were made immediately after mounting when cellular details, especially the nucleoli, are clearest. Motoneurons were identified using the criteria of Prestige⁴, which are based on position, alignment and size. Motoneurons with nucleoli were counted in every third section and no corrections were made for nucleolar splitting which probably occurs rarely⁴. Medial motor column neurones were not counted as they do not supply the limb. HRP labelling was assessed 2–3 weeks later after partial drying of the DPX to maximise visibility of the label.

Any competition should have shown as a negative correlation with ipsilateral counts falling as the contralateral projection increased. Conversely, the fact that ipsilateral counts were not increased above normal when the contralateral projection was small shows that the operation itself had not created a 'super-limb' with an increased motoneurone-supporting capacity.

Although it has been shown that the limb does not limit the number of survivors, a form of peripheral competition may still be postulated in which the survival rate is decided, not by the amount of space or trophic factors in the limb, but by a variable quality intrinsic to the ventral horn cells themselves. For example, using the analogy of territorial aggression, 'strong' ventral horn cells may acquire all the synaptic sites or trophic factors at the expense of the 'weak' cells. This idea was tested recently in *Xenopus* by allowing some ventral horn cells which normally die to have sole occupation of a part of the limb. Nevertheless, their deaths were not prevented and the part of the limb was left uninervated¹⁵, proof that at least some cell deaths are not due to peripheral competition. This evidence and the present results militate strongly against any form of peripheral competition determining motoneurone numbers.

Although the limb may not directly control numbers it remains indisputable in both *Xenopus*⁴ and chick⁵ that ventral horn cells must make contact with it to survive. Indeed, concurrent experiments in *Xenopus* (unpublished) have shown that the contact must be made with regions of the limb for which the motoneurons have been specified. This may provide one explanation for the present result. Specification may be so precise that only the minority of ventral horn cells succeed in finding their region, but all those that do, survive.

Control of motoneurone numbers may also be exercised outside the limb. An intriguing possibility is that the ventral horn cells may yet be competing (for example, for afferent connections, blood supply) but in the spinal cord, not in the limb. Some authors have also conjectured that not all ventral horn cells are presumptive adult motoneurons capable of long-term survival. Apart from some work showing that all ventral horn cells have axons at least as far as the ventral root¹⁶, this question has not been studied in *Xenopus*. However, extensive investigations in the chick embryo have not so far shown any differences between ventral horn cells destined to live or die¹⁷.

We are left with the problem of how supernumerary limbs prevent some ventral horn cells from dying^{6–10}. The usual interpretation is that the increased limb field allows more competing cells to survive^{2,7}. With peripheral competition now in doubt, this interpretation is less attractive. Others should instead be considered more seriously, including effects of the supernumerary limbs on ventral horn cell specification¹⁸, or on the central control of their survival. Tests of these possibilities should be feasible.

Other interesting questions arising from this study concern the electrophysiology of the motoneurons projecting to the single limb, how they distribute their innervation to the muscle fibres and the implications for theories of axonal guidance. In the three frogs given HRP into the gastrocnemius, normal projections were found from both ventral horns. Further evidence of normal somatotopy would argue that at least in *Xenopus*, axons are actively guided into the limb and not just channelled fortuitously by mechanical or geographical factors as recent work in the chick embryo seems to suggest^{19,20}. The single limb preparation should be an excellent model for studying various aspects of developing limb innervation.

I thank Dr L. D. Beazley for comments and Mr S. B. Baker for technical work. Support was provided by the National Health and MRC of Australia, the Muscular Dystrophy Research Association of Western Australia, and the TVW Telethon Foundation.

Opiate receptors influence vasopressin release from nerve terminals in rat neurohypophysis

L. L. Iversen, S. D. Iversen & F. E. Bloom

A. V. Davis Center for Behavioural Neurobiology, Salk Institute, La Jolla, California 92037, and MRC Neurochemical Pharmacology Unit, Department of Pharmacology, University of Cambridge, UK

A previous report described the existence of substantial amounts of enkephalin immunoreactivity and the occurrence of nerve terminals containing an enkephalin-like material in the pars nervosa of rat pituitary¹. It was suggested that an enkephalin innervation of the pars nervosa originating from the magnocellular hypothalamic nuclei might regulate the secretion of neurohypophyseal hormones. The results of the present studies support this hypothesis, as we find that a stable enkephalin analogue (D-Ala², D-Leu⁵-enkephalin) inhibits the calcium-dependent release of vasopressin evoked by electrical stimulation of the rat pituitary stalk *in vitro*. A similar inhibition of the stimulus-evoked vasopressin release is caused by morphine and β -endorphin, and the inhibitory effects of the enkephalin analogue can be reversed by naloxone. These findings suggest the possible existence of inhibitory opiate receptors on the terminals of vasopressin fibres in the pars nervosa.

The release of vasopressin from isolated pars nervosa/pars intermedia tissue fragments was studied using a method similar to those previously described^{2,3}. The pars nervosa with attached pars intermedia tissue was dissected from adult male Sprague-Dawley rats (Charles River; 150-200 g) and incubated in 0.5 ml Krebs-bicarbonate medium at 37°C continuously gassed with 95% oxygen:5% carbon dioxide. The pituitary stalk was drawn into the tip of a silver wire suction electrode to allow electrical stimulation and during periods of stimulation the gland was raised to the surface of the fluid. The medium was changed at

Table 1 Calcium dependence and tetrodotoxin sensitivity of vasopressin release

	n	Arg ⁸ -vasopressin (pg equivalents per min)	
		Resting release	Stimulation-evoked release
Control	18	93 ± 24.7	1,703 ± 268.7
Ca ²⁺ -free	4	140 ± 46.7	60 ± 7.7
Tetrodotoxin 1 µg ml ⁻¹	4	127 ± 13.3	83 ± 18.0

Rat pituitary pars nervosa fragments were incubated for 45 min before collecting 15-min fractions to assay resting release of vasopressin and release evoked by electrical stimulation of the pituitary stalk (evoked release = average vasopressin release during 15 min stimulation sample + 15 min post-stimulation period, see Fig. 1). Mean values ± s.e.m. for number of experiments (n) indicated.

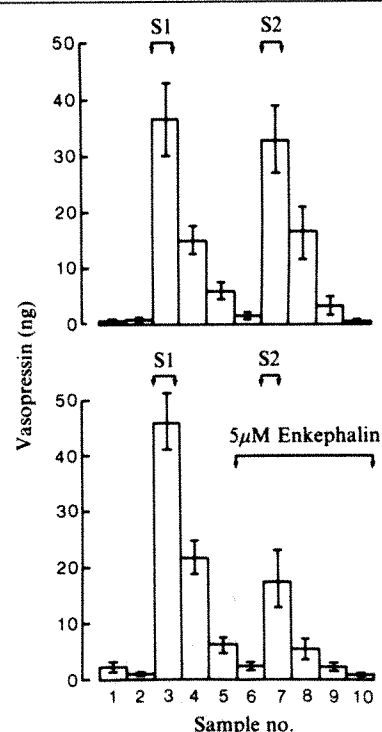

Fig. 1 Release of immunoreactive vasopressin from rat pituitary *in vitro* and inhibition by a stable enkephalin analogue. Rat pituitary pars nervosa/pars intermedia fragments were attached by the pituitary stalk to suction electrodes and incubated in Krebs-bicarbonate medium for 60 min before starting to collect sequential 15-min samples. During the experiment each gland was subjected to two periods of electrical stimulation (S1 and S2) through the pituitary stalk (30 V, 0.2 ms duration, 30 Hz in 10-s trains with 10-s intervals between trains for a total of 10 min). In 14 control experiments (a) the release of the vasopressin evoked during S2 was similar to that observed during S1. Addition of a stable enkephalin analogue (D-Ala², D-Leu⁵-enkephalin = 5 µM ENKEPHALIN) 15 min before S2 (b, eight experiments). Vasopressin was measured by radioimmunoassay and results are expressed as ng Arg⁸-vasopressin equivalents; each value is the mean ± s.e.m. for the number of experiments indicated.

15-min intervals and vasopressin was measured by a radioimmunoassay procedure, using ¹²⁵I-vasopressin (NEN), a rabbit antibody to vasopressin (Calbiochem-Behring) and synthetic Arg-vasopressin as standard. The immunoassay had a sensitivity limit of 0.2-0.4 pg per sample and there was no detectable cross-reactivity with oxytocin in amounts up to 200 ng. None of the test substances used had any effects on the vasopressin radioimmunoassay. Incubation samples were neutralised (10 µl 0.2 M HCl) and stored frozen; they were diluted at least 10-fold with assay buffer before assay. As the spontaneous release of vasopressin was initially high, but subsequently declined to low levels, the first period of electrical stimulation was carried out after a preincubation period of 60 min. Phasic rather than continuous stimulation was chosen as this more closely mimics the natural firing pattern of the vasopressin neurones, and leads to an enhanced release of vasopressin *in vitro*⁴. In these conditions the resting release of vasopressin in 14 control experiments was 0.6 ± 0.13 ng Arg⁸-vasopressin equivalent in 15 min, corresponding to a spontaneous release rate of approximately 0.004% of total tissue content per min (tissue content at the end of experiment = 1,072.5 ± 137.0 ng vasopressin per gland, mean ± s.e.m., n = 14). Phasic electrical stimulation of the pituitary stalk (S1) led to an increase of more than 60-fold in vasopressin release, and a total of 51.2 ± 8.94 ng vasopressin (mean ± s.e.m., n = 14) was recovered in the stimulation sample and in the sample collected in the 15-min period after stimulation (Fig. 1). A second period of electrical stimulation (S2) 45 min after the first elicited almost the same release of vasopressin (49.1 ± 10.59 ng) as the first. In subsequent experiments

therefore, test agents were introduced 15 min before the second period of stimulation, and results were expressed as the ratio of vasopressin released during the two stimulation periods (S2/S1).

Control experiments confirmed²⁻⁴ that the stimulation-evoked release of vasopressin was completely abolished by the addition of tetrodotoxin ($1 \mu\text{g ml}^{-1}$) or by removal of calcium ions from the incubation medium (Table 1). Addition of the stable enkephalin analogue D-Ala²,D-Leu⁵-enkephalin (DADLE)⁵ ($5 \mu\text{M}$) before the second stimulation period led to more than a 70% inhibition of the stimulus-evoked release of vasopressin (Fig. 1, Table 2), without any significant change in the spontaneous efflux of vasopressin. Similar inhibitory effects on the stimulation-evoked release of vasopressin were seen after addition of morphine ($10 \mu\text{M}$) or β -endorphin ($2 \mu\text{M}$). The inhibitory effect of DADLE was completely reversed by simultaneous addition of the opiate antagonist drug naloxone ($1 \mu\text{M}$) (Table 2). Naloxone alone, however, had no significant effect on the spontaneous or evoked release of vasopressin; γ -aminobutyric acid (GABA) ($50 \mu\text{M}$) and somatostatin ($1 \mu\text{g ml}^{-1}$) were also without effect (Table 2).

The results show that activation of opiate receptors in the rat neurohypophysis can inhibit the stimulus-evoked release of vasopressin from neurosecretory nerve terminals. These findings suggest that opiate receptors may exist on the terminals of vasopressin neurones in the pars nervosa, which possesses a high density of opiate binding sites⁶. The effects of opiates are selective, as two other biologically active compounds that occur in and can be released from the pars nervosa, GABA⁷ and somatostatin⁸, had no effects on vasopressin release. The present findings are at first sight difficult to reconcile with several previous reports which suggest that the administration of opiates or endorphins *in vivo* leads to an enhanced release of vasopressin from the pituitary⁹⁻¹². However, this general conclusion has been questioned¹³, and recent studies have reported that systemically or centrally administered opiates and endorphins can lead to a reduction in vasopressin immunoreactivity in rat plasma^{14,15}. In addition to the inhibitory effects on vasopressin release from neurohypophysis reported here, opiates may act centrally to inhibit the firing of vasopressin neurones (ref. 16 and G. Clarke and P. Wood, personal communication). Furthermore, the present results are complementary to those of Clarke *et al.*¹⁷, who recently reported that intraventricularly administered morphine led to a suppression of oxytocin release from rat pituitary, and suggested the existence of opiate receptors on oxytocin-containing nerve terminals in the neurohypophysis. Our findings confirm a previous report that β -endorphin failed to affect the spontaneous release of vasopressin from rat pars nervosa *in vitro*¹², although these authors did not examine the

effects of endorphin on the stimulus-evoked release of vasopressin. The concept that opiate receptors may exert an inhibitory influence on the release of a biologically active substance from nerve terminals agrees with other studies which have shown that opiate receptors in other parts of the nervous system control the release of acetylcholine¹⁸, noradrenaline¹⁸ and substance P¹⁹. The possible physiological function of such a control mechanism in the neurohypophysis remains to be defined.

We thank Dr J. Kelly for advice on the pituitary release, Dr J. Rivier for supplying samples of Arg⁸-vasopressin, somatostatin and β -endorphin, Dr S. Wilkinson (Wellcome) for D-Ala²,D-Leu⁵-enkephalin, Endo Laboratories for naloxone hydrochloride and Raana Azad for performing the vasopressin assays. The studies were supported by USPHS grant DA-01785.

Multiple opiate receptor sites on primary afferent fibres

H. L. Fields, P. C. Emson, B. K. Leigh, R. F. T. Gilbert & L. L. Iversen

MRC Neurochemical Pharmacology Unit, Department of Pharmacology, University of Cambridge, Medical School, Hills Road, Cambridge CB2 2QD, UK

In addition to their actions at supraspinal sites, opiates can act directly at the spinal cord level to produce analgesia¹⁻³. Opiate receptors and enkephalins are found in abundance in the dorsal horn of the spinal cord, in the region of termination of small-diameter primary afferents⁴⁻⁶. Furthermore, there is evidence that exogenously administered opiates or endogenous enkephalins act both on postsynaptic receptors in dorsal horn and presynaptically to block transmitter release from nociceptive primary afferent terminals⁷⁻¹⁰. The possibility of these two distinct sites of opiate action in dorsal horn is of particular interest in view of recent evidence for the existence of multiple opiate receptors¹¹⁻¹³. On the basis of differences in the rank orders of potency of opiate alkaloids and opioid peptides observed in different tissues, Lord *et al.*¹⁴ have proposed two categories of opiate receptor, μ and δ , and these can be differentiated in binding studies, provided that selective radioligands are used in the appropriate experimental conditions¹⁵⁻¹⁸. Here we have used the selective radioligands ³H-morphine (μ sites) and ³H-D-Ala²,D-Leu⁵-enkephalin (δ sites) to examine directly in rat the distribution and binding characteristics of opiate receptors on dorsal root and in various regions of the adjacent spinal cord. Primary afferent tissue (dorsal root) and dorsal horn were found to contain μ and δ opiate binding sites with a relatively high proportion of μ sites. Partial destruction of small-diameter primary afferents after cutting the sciatic nerve led to a significant reduction in both μ and δ binding sites on dorsal roots, suggesting that both types of opiate receptors may exist on small-diameter primary afferents.

Table 2 Effect of opiates and other substances on stimulation-evoked release of vasopressin from rat pars nervosa

	n	S2/S1 (mean \pm s.e.m.)
Control	14	0.99 \pm 0.12
D-Ala ² ,D-Leu ⁵ -enkephalin ($5 \mu\text{M}$)	8	0.28 \pm 0.08*
Morphine sulphate ($10 \mu\text{M}$)	5	0.28 \pm 0.10*
β -Endorphin ($2 \mu\text{M}$)	3	0.44 \pm 0.14*
D-Ala ² ,D-Leu ⁵ -enkephalin ($5 \mu\text{M}$) + naloxone ($1 \mu\text{M}$)	7	1.06 \pm 0.26
Naloxone ($1 \mu\text{M}$)	5	0.97 \pm 0.24
Somatostatin ($1 \mu\text{g ml}^{-1}$)	3	0.98 \pm 0.18
GABA ($50 \mu\text{M}$)	3	1.14 \pm 0.29

After a control period of electrical stimulation (S1), test substances were added to the incubation medium 15 min before a second period of electrical stimulation (S2). Results are expressed as the ratio S2/S1, representing the total amounts of vasopressin released (during the stimulation period and in post-stimulation sample) by the two stimulation periods. Values are means \pm s.e.m. for the number of experiments indicated (n).

* $P < 0.01$ compared with control.

Using a modification of the approach described by Chang and Cuatrecasas¹⁸, commercially available high-specific activity tritium-labelled morphine and D-Ala²,D-Leu⁵-enkephalin at low concentrations were chosen as selective radioligands for μ and δ opiate binding sites, respectively^{17,18}. As described by Lord *et al.*¹⁴, μ receptors are characterised by their high affinity for morphine and related alkaloids and for the antagonist drug naloxone, whereas δ receptors preferentially recognise enkephalins and are relatively resistant to naloxone. Preliminary experiments were carried out using rat corpus striatum, a region of the central nervous (CNS) system known to contain a high density of both μ and δ binding sites¹⁷. There was a considerable amount of specific binding (defined by the use of 1 μ M levorphanol) of both radioligands in membrane preparations from striatum; at low concentrations of each ligand (≤ 1 nM) specific binding accounted for 80–90% of total binding. Saturation analyses over the concentration range of 0.1–15.0 nM for ³H-D-Ala²,D-Leu⁵-enkephalin indicated the presence of a single binding component on Scatchard plots, with an apparent K_d of 2.4 nM (Table 1). Similar analyses for ³H-morphine suggest the existence of both low- and high-affinity binding components, but over a restricted range of low concentrations of ligand (0.2–1.5 nM) a single high-affinity component predominated, with an apparent K_d of 1.2 nM. The potency of various opiates, opiate antagonists and opioid peptides in competing for ³H-morphine or ³H-D-Ala²,D-Leu⁵-enkephalin binding was determined, using the approach described by Terenius and Wahlström¹⁶ in which a low concentration of radioligand (0.5 nM) was combined with the same concentration of the second unlabelled ligand to

Table 1 Properties of ³H-morphine and ³H-D-Ala²,D-Leu⁵-enkephalin binding in rat striatum and spinal cord

	Striatum		Spinal cord	
	³ H-morphine	³ H-D-Ala, D-Leu-enkephalin	³ H-morphine	³ H-D-Ala, D-Leu-enkephalin

Met ⁵ -enkephalin	4.0	2.6	—	—
Leu ⁵ -enkephalin	5.2	1.0	—	—
Levorphanol	1.0	11.0	0.9	2.1
Morphine	2.5	240.0	3.0	68.0
Naloxone	1.8	34.0	3.5	14.0
Diprenorphine	0.4	0.16	—	—
Ethylketocyclazocine	3.4	7.4	—	—

Corpus striatum or whole spinal cord were dissected from adult male Sprague-Dawley rats and homogenised in 50 vol ice-cold 50 mM Tris-HCl buffer, pH 7.4 (Polytron, setting 7, 15 s). The homogenate was centrifuged (4°C, 50,000g, 15 min) and resuspended in 50 vol Tris buffer (Polytron, setting 7, 15 s). After incubation for 45 min at 37°C, to digest endogenous enkephalins, membrane fragments were collected by centrifugation and suspended in ice-cold Tris buffer at a final concentration (in terms of original tissue wet weight) of 10 mg ml⁻¹ (striatum) or 20 mg ml⁻¹ (spinal cord). Samples (1 ml) of the membrane suspension were incubated with ³H-morphine ([1(n)-³H]morphine; specific activity 27 Ci mmol⁻¹; Radiochemical Centre) or ³H-D-Ala²,D-Leu⁵-enkephalin (D-Ala²,D-Leu⁵-[tyrosyl-3,5-³H]enkephalin; specific activity 48 Ci mmol⁻¹; Radiochemical Centre) for 20 min at 30°C. The labelled membranes were collected by rapid filtration on Whatman GF/B glass fibre filter disks, and washed with 2 \times 5 ml of Tris buffer. After soaking the filters for at least 2 h in 4 ml ethoxyethanol, radioactivity was measured by liquid scintillation counting after addition of 10 ml scintillation fluid. Nonspecific binding was defined by parallel incubations in the presence of 1 μ M levorphanol. Incubations and non-specific blanks were always carried out in triplicate. The protein content of individual membrane preparations was determined by the method of Lowry *et al.* To avoid losses of ³H-enkephalin due to adsorption to glassware and pipettes the stock solution of the labelled peptide was diluted in plastic tubes with Tris buffer containing bovine serum albumin (Sigma; crystalline grade) 0.1 mg ml⁻¹ in preparing a stock solution; this was further diluted 1:500 (v/v) in the final incubations. IC₅₀ values were determined at 0.5 nM radioligand concentration as illustrated in Fig. 1. K_d values were determined by Scatchard analysis of specific binding measured in triplicate at 4–6 ligand concentrations in the concentration range 0.1–15.0 nM for ³H-D-Ala²,D-Leu⁵-enkephalin, and 0.2–1.5 nM for ³H-morphine.

Table 2 Distribution of opiate binding sites in rat spinal cord, striatum and spinal roots

	Specific binding (fmol per mg protein)		
	³ H-morphine	³ H-D-Ala, D-Leu-enkephalin	Binding ratio
Dorsal root	8.9 \pm 0.45(7)	2.7 \pm 0.22(6)	3.2 \pm 0.22(6)
Dorsal horn	8.1 \pm 0.66(4)	4.9 \pm 0.79(4)	1.7 \pm 0.28(4)
Ventral horn	3.6 \pm 0.56(4)	3.6 \pm 0.20(4)	1.0 \pm 0.11(4)
Ventral root	2.2 \pm 0.31(3)	<1.0(3)	—
Sciatic nerve	<1.0(5)	<1.0(5)	—
Corpus striatum	24.0 \pm 2.54(7)	44.2 \pm 2.69(7)	0.5 \pm 0.04

Spinal tissues were removed following laminectomy in stunned decapitated rats. Roots were dissected from L4–L6 ganglia to cord entry, sciatic nerve from notch to knee. Each cord half was divided at the level of the canal into dorsal and ventral parts. Each measurement included pooled tissue from 6 to 10 adult male rats (250–250 mg tissue). All measurements were made at 0.5 nM concentrations of radioligand. Specific binding, defined using 1 μ M levorphanol, was 40–60% of total for ³H-morphine and 20–45% for ³H-D-Ala²,D-Leu⁵-enkephalin. In some cases the specific binding of radioligands was less than 1 fmol per mg protein and was considered to be below the limit for accurate measurement (<20% specific binding). Using the Student's *t*-test, the amount of ³H-morphine binding in ventral horn differed significantly from that in dorsal horn ($P < 0.005$) and dorsal root ($P < 0.001$). For the binding ratios, dorsal horn differed significantly from dorsal root ($P < 0.01$) and ventral horn ($P < 0.01$). Other comparisons did not show significant differences. Statistical comparison with ventral root and sciatic nerve were not made. Values are means \pm s.e.m. for the number of experiments indicated in brackets. The binding ratio represents binding of each radioligand at a single concentration (0.5 nM) and gives a relative indication of the proportions of μ and δ binding sites.

ensure that drug potencies were compared in conditions of similar basal receptor occupancy.

The results obtained with the various drugs tested (Fig. 1, Table 1) were similar to those reported by Chang and Cuatrecasas¹⁸, who used ³H-dihydromorphine or ³H-naloxone and ¹²⁵I-D-Ala²,D-Leu⁵-enkephalin. Provided the tritium-labelled compounds were used at concentrations below their K_d values (0.5 nM), they seemed to serve as selective ligands for μ and δ opiate receptors, respectively. Morphine itself was the best discriminating drug, as it was ~100 times more potent in competing for the binding of ³H-morphine (μ sites) than for ³H-D-Ala²,D-Leu⁵-enkephalin (δ sites, Fig. 1). Naloxone was ~20 times more potent on μ than on δ sites, and nonradioactive D-Ala²,D-Leu⁵-enkephalin, Met-enkephalin and Leu-enkephalin were more potent on δ than on μ sites. Because neither ³H-morphine nor ³H-D-Ala²,D-Leu⁵-enkephalin are completely selective ligands for μ and δ sites, saturation analysis cannot provide accurate values for the absolute numbers of μ and δ sites in particular regions of the CNS. However, the use of these radioligands at low concentrations provides a useful index of the ratio of μ to δ sites. The present results suggest a preponderance of enkephalin (δ) receptors over morphine (μ) receptors in corpus striatum.

By using homogenates of whole rat spinal cord, binding sites for both radioligands could be detected with K_d values and inhibitor sensitivities similar to those observed in striatum (Table 1). Although the density of binding sites in spinal cord was much lower than in striatum, there was significant binding of both the peptide (δ) and alkaloid (μ) agonists on pooled samples of lumbosacral dorsal roots and in dorsal and ventral horn. Binding sites for either ligand were barely detectable on ventral root or peripheral nerve (Table 2). Compared with striatum, where δ binding predominated (with a μ/δ ratio of about 0.5), there was relatively more μ binding in dorsal root and dorsal horn, with μ/δ binding ratios of 3.2 and 1.8, respectively (Table 2). To determine whether the ³H-enkephalin (δ) binding in dorsal roots represented a possible cross-reactivity of this ligand with μ receptors, displacement studies were carried out with nonradioactive morphine. Addition of 25 nM nonradioactive morphine caused an 85% inhibition of ³H-morphine binding in

Fig. 1 Determination of IC_{50} values for morphine (triangles) and naloxone (circles) as inhibitors of specific binding of 3H -morphine (solid circles and triangles) and 3H -D-Ala,D-Leu-enkephalin (open circles and triangles, each at 0.5 nM) in rat striatal membrane preparation. Each point represents the mean of triplicate determinations. All tubes for 3H -morphine binding measurements also contained 0.5 nM nonradioactive D-Ala,D-Leu-enkephalin, and tubes for 3H -enkephalin binding contained 0.5 nM nonradioactive morphine to ensure similar basal receptor occupancy¹⁶. Ordinate: per cent inhibition of specific 3H -labelled radioligand binding (defined by 1 μM levorphanol) probit scale; abscissa: log concentration of nonradioactive morphine or naloxone.

dorsal root samples, but less than a 10% inhibition of 3H -D-Ala,D-Leu-enkephalin binding ($n=2$). Because of the small amounts of dorsal root tissue obtainable, it was not possible to carry out detailed saturation analyses or complete drug displacement curves. However, the results clearly demonstrate that both types of opiate site are present on primary afferent fibres. Furthermore, the observation that binding ratios for the two types of agonist differ significantly on dorsal root and dorsal horn supports the idea that there are separate pre- and post-synaptic populations of opiate receptor, with a relatively greater proportion of δ -type receptors on postsynaptic elements in the dorsal horn.

To determine whether the opiate binding sites are present on small-diameter primary afferent fibres, further experiments were carried out after cutting the sciatic nerve. There is evidence that this procedure leads to a loss predominantly of small-diameter afferent fibres in the dorsal roots¹⁹⁻²¹. In three groups of 10 rats, the sciatic nerve was cut 1 month before dissection of the L5 and L6 dorsal roots, which were pooled to prepare membranes for ligand binding studies. The results showed a significant reduction in both μ and δ binding sites on the dorsal roots after sciatic nerve section (Table 3).

The present results provide the first direct evidence that primary afferents have significant numbers of opiate receptor sites on their central processes. This conclusion is consistent with previous findings of a depletion of opiate binding sites in dorsal horn following damage to primary afferents^{22,23}. Autoradiographic evidence has also shown that the central processes of vagus nerve afferents, which are predominantly unmyelinated, bear opiate receptors²⁴. Furthermore, administration of capsaicin to neonatal rats causes a relatively selective loss of small-diameter primary afferents²⁵ and this procedure leads to a

reduction of opiate receptors in dorsal horn^{26,27}. These findings are consistent with neurophysiological evidence that opiates can act directly on the terminals of small-diameter primary afferent fibres^{28,29} and exert a selective inhibitory effect on nociceptive input to dorsal horn neurones^{9,10}, adding further support to the hypothesis that opiates may act presynaptically to block pain transmission at the spinal cord level.

H.L.F. was a fellow of the Josiah Macy Foundation and supported by PHS research grant DA 01949. R.F.T.G. is an MRC Scholar. Nonradioactive D-Ala,D-Leu-enkephalin was donated by Wellcome Laboratories and naloxone by Endo Laboratories.

Changes in composition and activity of microtubule-associated proteins during brain development

A. Mareck, A. Fellous, J. Francon & J. Nunez

Unité de Recherche sur la Glande Thyroïde et la Régulation Hormonale, INSERM, Equipe de Recherche 233 CNRS, 78, rue du Général Leclerc-94270 Bicetre, France

The onset of neuronal differentiation is characterised by intensive neurite growth; because microtubule formation is strictly required during this process¹⁻³, *in vitro* assembly of the tubulin present in the rat brain has been studied at different stages of development⁴: the rate of assembly is very slow in the early stages and increases progressively with age from birth until adulthood. Other data⁴ also suggested that the limiting factor in the young brain is the amount or activity of one or several of the minor components which co-polymerise into microtubules with tubulin. We show here that both the composition and the activity of the microtubule-associated proteins change during the time course of rat brain development.

Rat brain supernatants were prepared at two stages of post-natal development, 3 days after birth (that is, at the beginning of the critical period of development in this species) and at day 35 (near adulthood). The tubulin present in both supernatants was allowed to assemble *in vitro* in the conditions described by

Table 3 Reduction of μ and δ binding in dorsal roots 1 month following sciatic cut

	Specific binding (fmol per mg protein)	
	3H -morphine (μ)	3H -D-Ala,D-Leu-enkephalin (δ)
Normal control (Table 2)	8.9 \pm 0.45(7)	2.7 \pm 0.22(6)
Sciatic cut	5.9 \pm 1.18(3)	1.3 \pm 0.05(3)
% Reduction	-34%	-51%

The sciatic nerve was cut 30 days before removal of the dorsal roots (L5, L6). The cut side significantly differed from control ($P < 0.05$ for μ , $P < 0.005$ for δ).

Fig. 1 Analysis by SDS gel electrophoresis of microtubule proteins prepared from adult (a) and 3-d-old (b) rat brain. Microtubules were obtained by the procedure described by Shelanski *et al.*⁵ slightly modified⁶. The microtubule pellets were depolymerised by cold in the presence of NaCl 0.75 M. Samples of these preparations were made up with 1% SDS and 1% dithiothreitol and then heated to 100°C for 5 min. Aliquots of these samples containing 11 µg of microtubule proteins were electrophoresed according to the method of Weber and Osborn⁷ on a slab gel with a 4–15% gradient of polyacrylamide. The gels stained with Coomassie blue are represented for the two preparations of microtubule proteins.

Shelanski *et al.*⁵ slightly modified⁶. At the end of the incubation period the microtubules were pelleted by centrifugation, washed and analysed by polyacrylamide gel electrophoresis in the conditions described by Weber and Osborn⁷. Fig 1a and b, show that, in addition to tubulin, several minor components are present in both 'young' and 'adult' preparations. Among these associated proteins one group with high molecular weight (~300,000) contains two components similar to MAP₁ and MAP₂ (or HMW₁ and HMW₂) first described by Murphy and Borisov^{8,9}. The young preparation contains both MAP₁ and MAP₂; several analyses show that the percentage of these entities does not differ from that measured in adult microtubules (MAP₁ + MAP₂/tubulin = 16% in the young preparation and 17.5% in the adult one). Another group of MAPs, not well separated from tubulin and similar to the τ protein complex first isolated by Weingarten *et al.*¹⁰, is seen in the microtubules of both ages. The τ complex is thermostable¹⁰, and so, to study better this group of microtubule-associated proteins at both ages, purification was achieved as previously described¹¹ by thermic treatment of the *in vitro* assembled microtubules. Tubulin and MAP₁ were eliminated during this treatment and the other microtubule-associated proteins could be analysed at a much higher concentration by polyacrylamide gel electrophoresis. Figure 2a, which represents the analysis of the adult associated proteins, shows the presence of MAP₂ and the τ complex with its characteristic four closely spaced bands. With the young preparation MAP₂ is clearly present (Fig. 2b), but the pattern at the level of the τ complex is completely different: only two bands are present and none of them seem to be identical to any of the four bands present in the adult preparation. Identical results were found in four different experiments; moreover, after a second cycle of assembly the same protein pattern was found at the level of the τ complex, only two bands for the young preparation, with none of them being similar to any of the four closely spaced bands of the adult one. In addition, a control experiment was

carried out in the presence, throughout the procedure, of a protease inhibitor (phenylmethylsulphonyl fluoride) to rule out the possibility that the changes seen at the level of the τ complex are due to proteolytic breakdown of this or other (MAP₁, MAP₂)¹² fractions in the young preparation. Polyacrylamide gel electrophoresis revealed no marked differences in the protein patterns.

The activity of young and adult microtubule-associated proteins preparations in promoting tubulin assembly was also assayed. Pure adult tubulin was prepared by phosphocellulose chromatography^{11,13}; as previously shown, such tubulin does not assemble *in vitro* into microtubules even at high concentrations^{8,10,11,14,15}. A constant amount of pure tubulin was then incubated at 37°C in the presence of increasing concentrations of both young and adult associated proteins obtained by thermic treatment; Fig. 3a shows the time course of assembly. Clearly, the activity of the young microtubule-associated proteins was much lower than that of the adult one. Fig. 3b represents the relationship between initial rates of assembly and the concentration of young or adult microtubule-associated

Fig. 2 Analysis by SDS gel electrophoresis of thermostable microtubule-associated proteins (or MAPs) prepared from adult (a) and 3-d-old (b) rat brain. Thermostable MAPs were prepared by a thermic denaturation procedure previously described¹². Samples of MAPs containing 7 µg for 3-d-old rat brain preparation and 11 µg for adult rat brain preparation were electrophoresed in the conditions described in Fig 1 legend. The gels stained with Coomassie blue are represented for the two kinds of MAP preparations. T, Position of tubulin.

protein preparations. It can be seen that (1) the rate of assembly increases linearly with both preparations and remains always much lower for the young one, and (2) the minimal concentration of microtubule-associated proteins at which assembly may be observed (critical concentration¹⁶) is higher with the young than the adult preparation. Similarly, we have previously shown that the critical concentration of tubulin is higher with young crude brain supernatants than with adult ones⁴.

Because young microtubule-associated proteins contain MAP₂, which is active¹⁷ in promoting *in vitro* microtubule assembly, but not the normal τ fraction distribution, one may speculate that the activity present at the early stage is due to MAP₂ only. Conversely, one or both of the two peaks migrating in the τ region might have some activity. Purification of the slow and fast components present in the young preparation is in progress so that their activity may be tested separately.

From the data reported here, a model may be proposed to explain the role of increasing neurotubule assembly during brain development. Large pools of tubulin would be synthesised before the building up of the neuronal network^{18,19}; some or all

of this tubulin would be used at earlier stages of development to allow the formation of the mitotic spindle and therefore proliferation of the undifferentiated nerve cells. At the beginning of the differentiation phase, specific proteins with polymerising activity would appear in increasing amounts, thereby allowing fast microtubule assembly and intensive neurite growth. Thus, the transition between cell division and cell differentiation might be controlled, at least in part, by an increase in the polymerising activity or by qualitative changes in the factors required for

either pathway or both. Although further work is needed to decide on the requirements for microtubule assembly before nerve cell differentiation, our data support the idea that the appearance of specific factors is responsible for the increase in the rates of microtubule assembly during the critical period of brain development—during (and for) intensive neurite growth.

Received 16 November 1979; accepted 29 January 1980.

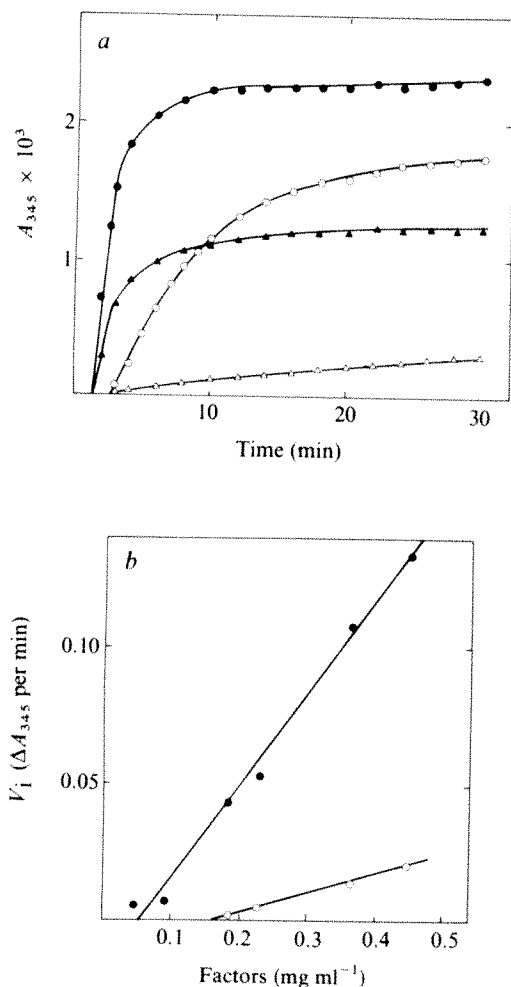

Fig. 3 Polymerisation-promoting activity of adult and 3-d-old rat brain thermostable microtubule-associated proteins on purified tubulin. Purified tubulin was obtained by a procedure previously described by Weingarten *et al.*¹⁰ but slightly modified: activated phosphocellulose was resuspended in the assembly buffer containing (in mM) morpholinethane sulphonate 100, MgCl_2 0.5, EGTA 1, EDTA 0.1, GTP 1 and 2-mercaptoethanol 1, pH 6.4. Tubulin was eluted from the column with the same buffer. The purity of the tubulin was controlled by SDS gel electrophoresis. The polymerisation-promoting activity of the two kinds of MAPs on purified tubulin were followed by the turbidimetric method described by Gaskin *et al.*¹⁶. Turbidimetry measurements (345 nm) during tubulin polymerisation, at 37 °C, in the assembly buffer previously described, were carried out using a Carl Zeiss PM 6KS spectrophotometer with an automatic thermostated four-sample changer. *a*, Time course of tubulin polymerisation in the presence of the two preparations of thermostable microtubule-associated proteins. Pure tubulin (0.95 mg ml^{-1}) was incubated in the presence of two concentrations of thermostable MAPs: 'adult' MAPs (\blacktriangle , $181 \mu\text{g ml}^{-1}$; \bullet , $452 \mu\text{g ml}^{-1}$) and '3-d-old' MAPs (\triangle , $181 \mu\text{g ml}^{-1}$; \circ , $452 \mu\text{g ml}^{-1}$). *b*, Relationship between initial rates of tubulin polymerisation and thermostable MAPs concentration. Initial rates of tubulin polymerisation (ΔA_{345} per min) were measured with increasing concentrations of adult MAPs (\bullet) and 3-d-old MAPs (\circ) and a constant tubulin concentration (0.95 mg ml^{-1}).

In vivo release of acetylcholinesterase in cat substantia nigra and caudate nucleus

Susan Greenfield, André Cheramy, Vincent Leviev & Jacques Glowinski

Groupe NB, INSERM U.114, Collège de France, 11, place Marcelin Berthelot, 75231 Paris Cedex 05, France

Acetylcholinesterase (AChE), which is known to inactivate acetylcholine (ACh), is present in great abundance in the substantia nigra, although ACh levels and choline acetylase activity in this region are relatively low¹. Nigral dopaminergic cell bodies and their dendrites also contain AChE^{2–4}. The functional significance of this enzyme in nigro-striatal dopaminergic neurones has been questioned^{1,4,5}. Earlier studies demonstrated an evoked release of AChE from unidentified central neurones into cerebrospinal fluid (CSF) in cats⁶, rabbits^{7,8} and dogs⁹. Later experiments have provided indirect evidence that the substantia nigra may contribute to a substantial amount of AChE detected: a unilateral nigral lesion in rabbits reduced AChE levels in the CSF, whereas electrical stimulation of the substantia nigra induced the opposite effect¹⁰. To investigate the possible release of AChE from dopaminergic dendrites and terminals we measured the *in vivo* release of this enzyme from the substantiae nigrae and caudate nuclei of cats implanted with four push-pull cannulae and compared it with that of dopamine (DA). DA is released from dendrites in the substantia nigra^{11,12} as well as nerve terminals in the caudate nucleus. Spontaneous AChE release was observed in the substantia nigra and in the caudate nucleus. Moreover, the application of potassium (30 mM) in one substantia nigra increased the local release of AChE. This was accompanied by remote changes in the enzyme release from the other three structures which differed from that seen for DA. The different patterns of responses observed for AChE and DA suggest that AChE may also originate from other neurones in both the substantia nigra and the caudate nucleus.

Push-pull cannulae were acutely implanted in the two caudate nuclei and substantia nigrae of halothane-anaesthetised cats as described previously¹¹. The four structures were superfused with artificial CSF at a rate of 1.2 ml h⁻¹ and the activity of AChE^{13,14}, nonspecific cholinesterase^{13,14}, and occasionally lactate dehydrogenase¹⁵, were estimated in successive 10-min fractions. In a second series of experiments the release of ³H-DA continuously synthesised from L-[3, 5-³H]-tyrosine (50 Ci mmol⁻¹, 50 μ Ci ml⁻¹) was estimated in the four structures¹⁶. In all cases, the stereotaxic placement of the tip of each push-pull cannula was verified histologically.

A spontaneous release of AChE, which remained constant throughout the experiment, was observed both in the substantia nigrae and in the caudate nuclei. The amount of AChE released was similar in both structures (Fig. 1). Nonspecific cholinesterase was also observed in superfusates, the levels being slightly higher than those of AChE in the substantia nigrae and in the caudate nuclei (Fig. 2).

The addition of potassium chloride (30 mM) for 10 min to the artificial CSF in the left substantia nigra markedly increased the local release of AChE, the maximal change being seen during the treatment. Surprisingly, this effect was accompanied by changes in AChE release in the three other structures. Whereas AChE release was also increased in the contralateral caudate nucleus, it was decreased in the ipsilateral caudate nucleus and the contralateral substantia nigra (Fig. 1). These distal changes were more sustained than those observed in the left substantia

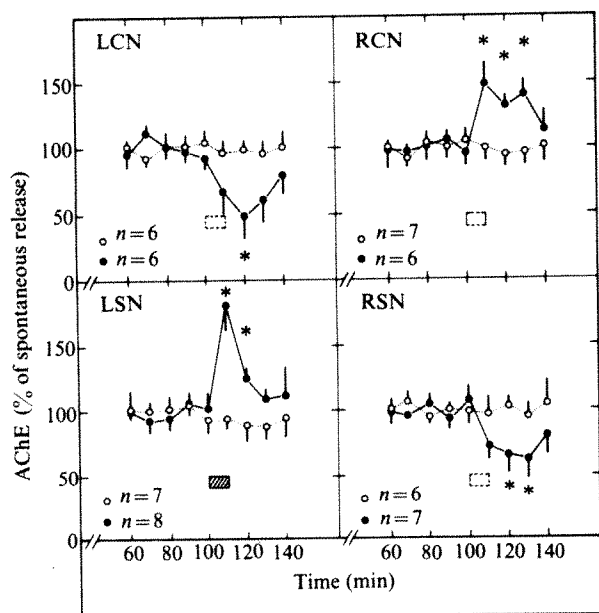

Fig. 1 Effects of the unilateral nigral application of potassium (30 mM) on the release of acetylcholinesterase (AChE) in both substantia nigrae and caudate nuclei. Four push-pull cannulae were simultaneously implanted in the left (LCN) and the right (RCN) caudate nuclei and in the left (LSN) and the right (RSN) substantia nigrae in anaesthetised cats. The four structures were superfused with an artificial CSF (1.2 ml h⁻¹) and AChE was estimated in 10-min successive superfusate fractions 60 min after the beginning of the superfusions. Potassium chloride (30 mM) was applied for 10 min in the LSN (hatched box with solid sides). The empty boxes with dotted sides represent the time during which potassium chloride (30 mM) was applied in the LSN. In each animal, and for each cannula, AChE in each successive fraction was expressed as a percentage of an average spontaneous release calculated from the five fractions collected (1.5 \pm 0.4, 1.8 \pm 0.5 and 1.7 \pm 0.3, 1.6 \pm 0.5 mU ml⁻¹ in the left and right substantia nigra and caudate nucleus respectively). Data are the mean \pm s.e.m. of results obtained with treated animals (●). $P < 0.05$ when compared with corresponding control values obtained in untreated animals (○).

nigra. In contrast, the release of nonspecific cholinesterase was not affected in the left substantia nigra or the other three structures (Fig. 2). As cat plasma contains a substantial amount of nonspecific cholinesterase (269 \pm 47 mU ml⁻¹, $n = 5$) as well as AChE (254 \pm 44 mU ml⁻¹, $n = 5$), the unchanged levels of nonspecific cholinesterase in superfusates would exclude a plasma origin for the observed changes in the release of AChE. Furthermore, the local release of AChE induced by potassium cannot be attributed to gross cell damage as the activity of lactate dehydrogenase (a cytoplasmic enzyme) in the superfusates remained unchanged during potassium application (before, 1.5 \pm 0.6 mU ml⁻¹; after, 1.5 \pm 0.6 mU ml⁻¹; $n = 4$). Therefore, the release of AChE is a specific process.

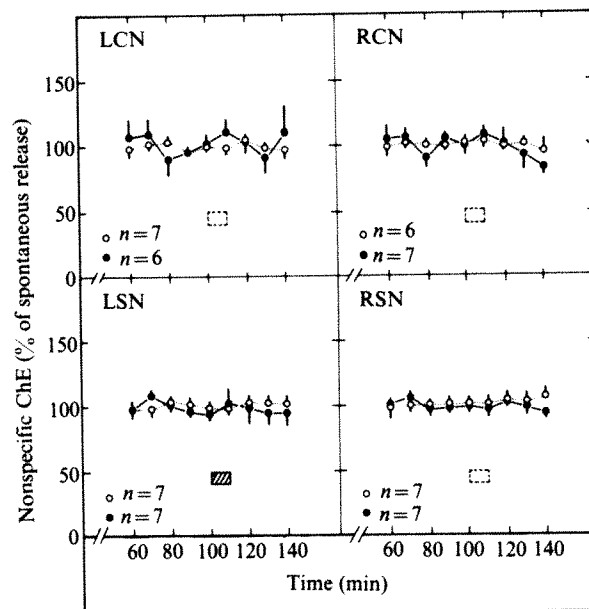

Fig. 2 Lack of effect of the unilateral nigral application of potassium (30 mM) on the release of nonspecific cholinesterase (ChE) in both substantia nigrae and caudate nuclei. During the experiments described in Fig. 1, we also measured nonspecific ChE in 10-min superfusate fractions and expressed the results as described in Fig. 1. The mean spontaneous release of nonspecific ChE in the left and right substantia nigra and in caudate nucleus were 2.3 \pm 0.5, 2.7 \pm 0.7 and 2.4 \pm 0.5, 2.6 \pm 0.6 mU ml⁻¹, respectively. Data are the mean \pm s.e.m. of results obtained with control (○) and treated cats (●). Boxes as in Fig. 1.

Studies on peripheral nerves and innervated tissue have indicated that AChE can be released through a process dependent on nerve activity^{17,18}. The distal changes in AChE release observed in the present study suggest that this phenomenon also occurs in the central nervous system (CNS). There is, therefore, little doubt that the release of AChE in the substantia nigrae and caudate nuclei has a physiological significance.

If AChE originates from nigro-striatal dopaminergic neurones, the simplest hypothesis is that AChE should behave as does DA released from dendrites and nerve terminals in the substantia nigra and caudate nucleus respectively. We thus measured the release of newly synthesised ³H-DA in the four structures. Confirming previous results, the unilateral nigral application of potassium (30 mM) enhanced the release of ³H-DA in both caudate nuclei, the effect being slightly less pronounced in the contralateral structure¹⁹. Moreover, potassium increased the release of ³H-DA not only locally in the left substantia nigra but also, surprisingly, in the right substantia nigra. Therefore, the nigral application of potassium induced opposite effects on AChE and ³H-DA release in the ipsilateral

caudate nucleus and the contralateral substantia nigra. These findings do not exclude the possibility of a release of AChE from dopaminergic dendrites and nerve terminals. However, in this case, the messages reaching the ipsilateral caudate nucleus or the contralateral substantia nigra and responsible for the release of AChE and DA would have to be mediated by different pathways, or the two compounds would have to display a differential response to the same signal. Another hypothesis is that AChE originates additionally or exclusively from non-dopaminergic neurones.

Although histochemical and biochemical studies have clearly indicated that a high proportion of AChE is present in dopaminergic cell bodies and their dendrites, nigral AChE also has another location. As shown in the rat substantia nigra, 6-hydroxydopamine lesions, which reduced tyrosine hydroxylase activity by at least 90%, decreased that of AChE by merely 43% (ref. 4). Furthermore, nigral AChE was only reduced by 44% after a local lesion with kainic acid, a neurotoxin which completely destroyed the dopaminergic neurones and is also known to induce the degeneration of other nigral neurones²⁰. AChE not contained in dopaminergic neurones does not originate from striato-nigral fibres, as a kainic acid lesion in the striatum failed to affect nigral levels of AChE²¹. Therefore, afferent fibres from other regions may be involved. The situation is even more complex in the striatum, as in the rat, the dopaminergic terminals only contain about 12% of the entire striatal AChE⁴. Furthermore, kainic acid lesions in the striatum

showed that about 50% of the enzyme was distributed in intrinsic neurones²¹. Therefore, as initially suggested by Shute and Lewis²², various afferent nerve fibres could be rich in AChE. In fact, electrolytic lesions of the centro-median nucleus of the thalamus reduced AChE as well as choline acetyltransferase activities by 50% in the cat²³. Hence, AChE measured in superfusates of the substantiae nigrae and the caudate nuclei could originate from sites other than dopaminergic dendrites or terminals.

Previously, we demonstrated the existence of complex mechanisms involved in the reciprocal control of the activity of the two nigro-striatal dopaminergic pathways. Asymmetric changes in DA release were observed in both caudate nuclei after modifications of DA transmission in one substantia nigra²⁴, or after unilateral sensory stimulation²⁵. These were associated with opposite asymmetric changes in the dendritic release of DA in both substantiae nigrae (reminiscent of the changes in AChE release, Fig. 1). In contrast, symmetric responses in DA release were seen in the two caudate nuclei during modifications of GABAergic or glycinergic transmission in one substantia nigra¹⁹. The existence of two different polysynaptic pathways was postulated to account for the asymmetric and symmetric effects observed¹⁹. Surprisingly, in the same experimental condition, that is, the unilateral nigral application of potassium, two opposite patterns of response for AChE and DA release were seen in the four structures, one being asymmetric (AChE) and the other symmetric (DA). This indicates once more that various neuronal pathways are involved in the reciprocal regulation of the activity of neurones innervating the two substantiae nigrae and caudate nuclei.

Although the origin of AChE released from the substantia nigra and the caudate nucleus has still to be elucidated, these results demonstrate that AChE can be released in the CNS through processes involving nerve activity. It has been suggested that AChE could have a role other than that of inactivating ACh^{1,5}. Before this hypothesis can be verified, it must be established whether or not the distal changes in the release of AChE induced by the unilateral nigral application of potassium are associated with changes in cholinergic transmission. Finally, whatever the mechanisms are in the control of AChE release from both substantiae nigrae and caudate nuclei, they should be taken into account in our subsequent understanding of neuronal interactions within the basal ganglia.

We thank Mr M. Desban for assistance with the histology. This work was supported by grants from INSERM (ATP 71.78.103), DRET (79.077) and Rhône-Poulenc S.G. is a recipient of an INSERM-MRC exchange fellowship, and A.C. is a research fellow of Rhône-Poulenc.

Received 12 December 1979; accepted 4 February 1980.

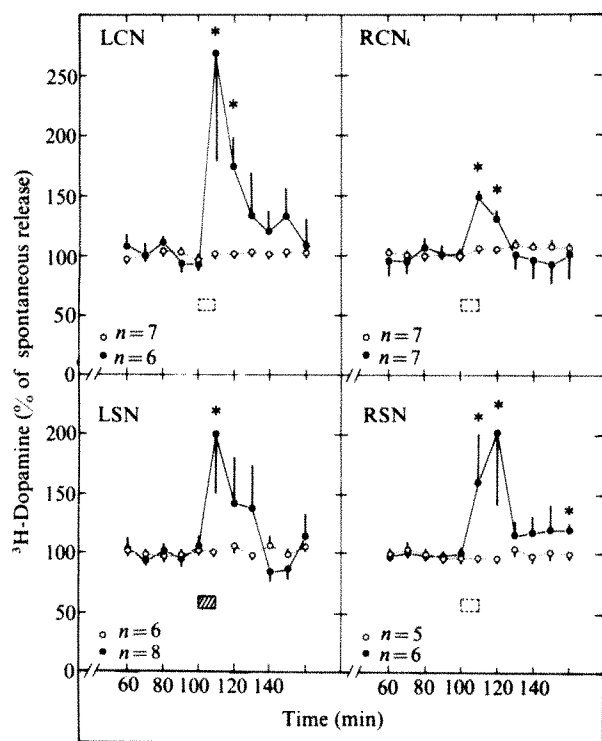

Fig. 3 Effect of the unilateral nigral application of potassium (30 mM) on the release of ³H-DA from the two substantiae nigrae and the two caudate nuclei. The experimental paradigm was essentially the same as described in Fig. 1, except that the artificial CSF delivered to the four push-pull cannulae contained L-[3, 5-³H]tyrosine (50 Ci mmol⁻¹, 50 μCi ml⁻¹, 1.2 ml h⁻¹) and that ³H-DA was estimated in 10-min successive superfusate fractions. Results were expressed as described in Fig. 1. The mean spontaneous release of ³H-DA in the left and right substantiae nigrae and left and right caudate nuclei being 0.65 ± 0.07, 0.57 ± 0.05 and 0.71 ± 0.08, 0.82 ± 0.10 nCi per 10 min, respectively. Data are the mean ± s.e.m. of results obtained with treated animals (●), *P* < 0.05 when compared with corresponding control values (○).

Glycocalyx is not required for slow inward calcium current in isolated rat heart myocytes

Gerrit Isenberg & Udo Klöckner

II. Physiologisches Institut, der Universität des Saarlandes, 6650 Homburg/Saar, FRG

The importance of the slow inward calcium current (I_{si}) in the excitation-contraction coupling process of cardiac muscle is well documented^{1,2}. The current can be attributed mainly to a calcium translocation from the extracellular space into the cell or a subsarcolemmal compartment of it^{3,4}. I_{si} has been suggested to have its source in and to be controlled by the surface coat of the sarcolemma (glycocalyx)⁵. The glycocalyx is destroyed in myocytes dissociated from adult heart tissue with solutions containing low calcium, collagenase and hyaluronidase^{6,7} (Fig. 1). By comparing the I_{si} data obtained in isolated myocytes with those reported for trabeculae or papillary muscles, we have now obtained evidence suggesting that the glycocalyx is not important in the genesis of I_{si} .

Whereas low calcium solutions are necessary for the dissociation of the cells, analysis of I_{si} requires superfusion with a Tyrode solution containing 2–4 mM calcium. The cells were isolated using the method described in ref. 8. Ventricles were minced into 3-mm coarse fragments and incubated in a solution composed of 130 mM NaCl, 5.4 mM KCl, 1.2 mM $MgSO_4$, 11 mM glucose, buffered with 5 mM HEPES-NaOH to pH 7.4 and containing 1 mg ml⁻¹ collagenase (Sigma, Type C 2139) and 1 mg ml⁻¹ hyaluronidase. The cells were separated from the supernatant at 30-min intervals; the remaining tissue fragments were reincubated. The Tyrode solution contained 150 mM NaCl, 5.4 mM KCl, 3.6 mM $CaCl_2$, 1 mM $MgCl_2$ and 10 mM glucose, buffered with 5 mM HEPES-NaOH to pH 7.4. On return from low to physiological calcium concentrations rat heart muscle cells are susceptible to the 'calcium paradox' (ref. 9): the cells develop a strong contracture, become spherical and finally die. This problem was overcome by incubating the isolated cells in high K^+ , substrate-enriched solutions before stepwise elevation of calcium to a final concentration of 3.6 mM. Preincubation was at room temperature for 40 min in solution A (0.5 mM EGTA, 2 mM ATP, 2 mM succinate, 2 mM pyruvate, 2 mM β -hydroxybutyrate, 11 mM glucose, 20 mM taurine, 1.2 mM $MgSO_4$ and 100 mM K_2HPO_4 , adjusted with KH_2PO_4 to pH 7.4) and for 20 min in solution B (1 mM $CaCl_2$ = 0.3 mM free Ca^{2+} ; 2 mM ATP, 2 mM succinate, 2 mM pyruvate, 1.2 mM $MgSO_4$, 100 mM KCl and 30 mM K_2HPO_4 , adjusted with KH_2PO_4 to pH 7.4).

In about 50% of the rod-shaped cells we measured resting potentials between -75 and -85 mV, values similar to those reported previously^{10,11}. The cells did not beat spontaneously but they contracted in response to a stimulus. The action potentials (Fig. 2) resembled those of intact rat heart ventricular tissue. Voltage-clamp experiments were carried out with a single microelectrode technique (see Fig. 3a). The membrane current

Fig. 2 Rat heart action potentials, intact tissue (a) compared with isolated myocytes (b, c). Isolated cells were viewed through an inverted microscope and impaled with 3 M KCl-filled microelectrodes. The configuration of the action potential differed appreciably: some cells displayed short-lasting action potentials (b) similar to those recorded from the intact trabecular (a), other cells displayed action potentials with a well pronounced plateau. Recordings from 20 cells revealed durations between 60 and 110 ms and amplitudes between 105 and 130 mV. All records were obtained in oxygenated Tyrode solution containing 3.6 mM $CaCl_2$. Temperature was 37 °C, stimulation frequency 1 Hz. Signals were digitised (10 bit per word) with a 2 K memory and stored on a digital tape recorder (ERDAC macrodyn).

evoked by a step depolarisation from -50 to 0 mV always started with a large initial outward surge and then declined within 10–12 ms to a minimum before reaching a steady outward level (Fig. 3b, see also Figs 4, 5). I_{si} was separated from the net current in the usual way^{3,4,12}. We subtracted the current waveform from the currents measured at the end of the clamp step and plotted this difference on a semi-log scale (Fig. 3d, ●). For clamp periods longer than 15 ms the plot shows a single exponential decay ($\tau_i = 10$ ms) which we associated with the inactivation of I_{si} . τ_i increased when the membrane was clamped to more positive potentials (Fig. 5c).

When inactivation of I_{si} was subtracted, the remaining currents changed during the first 15 ms of a clamp step with multiple time constants. An analysis of these currents (for time course of I_{si} activation) seemed impossible because of the limitations of the single electrode clamp technique (compare Fig. 3a).

An estimate of the voltage dependence of I_{si} amplitude was obtained by taking the difference in current between the quasi-steady state and the negative peak¹². The corresponding I - V curve (Fig. 4b, ●) reached a maximum at about 0 mV and crossed the V axis at a reversal potential of +50 mV ($+55 \pm 5$ mV; mean \pm s.e. from 5 cells). The compound D600 (ref. 13) greatly reduced I_{si} at all potentials (Fig. 4b, ×).

The voltage dependence of the steady-state activation (d_∞) and inactivation (f_∞) variables was analysed with the classical^{3,4} conditioning step program (Fig. 5a, b). The activation curve d_∞ started between -50 and -40 mV, increased e -fold per 22 mV (16 and 18 mV for two other cells) and reached saturation at 0 mV. Steady-state inactivation (f_∞) appeared between -40 and -30 mV, changed e -fold over 12 mV (11 and 12.5 mV for two other cells) and was complete around 0 mV. The curves intersect between -50 and 0 mV, suggesting a steady state I_{si} within this potential window.

Fig. 1 Transmission electron micrographs of myocytes isolated from adult rat hearts and superfused with Tyrode solution. a Shows a longitudinal section of a myocyte separated at the intercalated disk. The normal arrangement of the myofilaments and the mitochondria are typical of unassociated heart muscle. The transverse section b shows a structural intact sarcolemma; no glycocalyx or other associated surface structures are present. Transverse section c was taken for comparison from non-dissociated rat heart tissue; here the sarcolemma is superimposed by a glycocalyx shown as a lanthanum-stained lamina about 70 nm thick. Specimens were handled by a convenient technique^{6,7}. For staining the surface coat¹⁷ (b, c) Tyrode solution containing 2 mM $LaCl_3$ superfused the preparations 30 min before fixation. In addition, four samples were stained with ruthenium red; again (as in b), no glycocalyx was present at the surface of the isolated myocytes (not illustrated).

Fig. 3 Voltage-clamp experiments carried out with a single intracellular microelectrode. An electronic current pump¹⁸ injected current and simultaneously measured the membrane potential, electronic compensation minimised the current-induced voltage drop at the electrode resistance which was reduced by bevelling to 2.5 M Ω . (It has been shown¹⁹ that currents 2 nA through bevelled microelectrodes produce no tip polarisation or rectification.) *a*, Evaluation of the method. A second (current-free) microelectrode was impaled 50 μ m from the site of current injection; it measured the potential V_1 . Whereas V_0 , the potential of the current-injecting electrode followed the command within 0.2 ms, V_1 shows a delay of about 2 ms. Afterwards, V_1 is stable and deviates from V_0 by -2.5 mV. *b*, Membrane currents in response to a depolarising clamp step. The holding potential of -50 mV inactivated the fast sodium current before the 120-ms step to 0 mV. The validity of this method is indicated by the finding that I_{Na} remained constant when tetrodotoxin was added (5×10^{-5} g l⁻¹) or Na⁺ was replaced by tetramethylammonium or Tris. *c*, After having depolarised the cell for different periods of time, repolarisation back to -50 mV evoked an inward-directed tail current with an amplitude which reflects the conductance change at 0 mV. The envelope of the tails follows the same time course as the net current recorded at 0 mV (see Fig. 4*a*). *b* and *c* were photographed from an oscilloscope in storage mode. *d*, A semi-log plot of the difference between the current waveform and the current level at the end of the depolarising clamp step. The current record shown in *b* is analysed with the filled circles, the envelope of the tail currents (*c*) with the open circles.

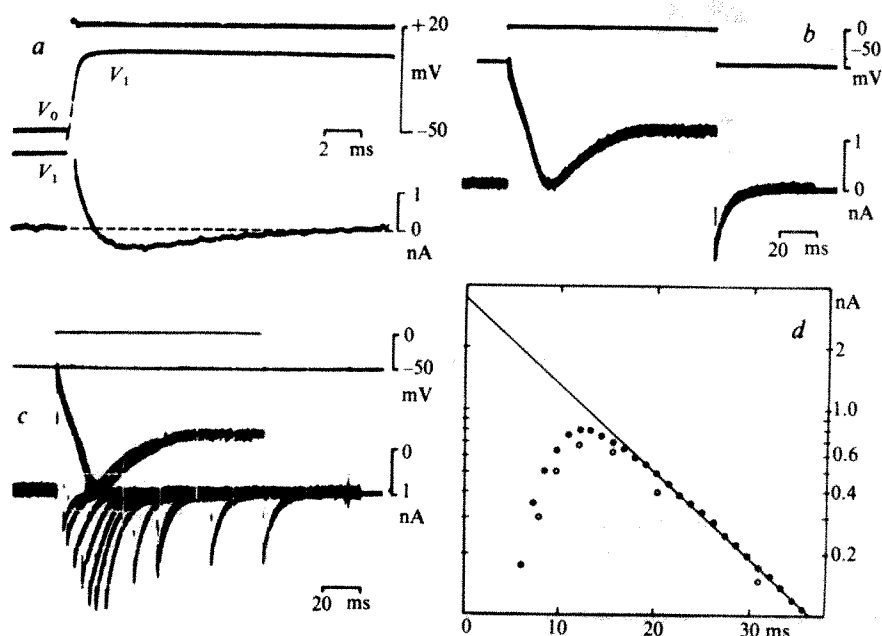

Fig. 4 (Above) Dependence of membrane currents on clamp potentials. The current tracings (*a*) were resolved into i_{Na} (outward current measured at the end of the 200-ms pulse which is not shown) and I_{Na} (peak negative current minus i_{Na}); values were plotted against the potential of the clamp step (circles in *b*). Exposure to 2 μ M D600 for 3 min (\circ , \bullet , before; $+$, \times , after application) strongly reduced I_{Na} (\times) but not i_{Na} ($+$). Currents evoked by a step to 0 mV before, 1 and 2 min after exposure to 2 μ M D600 are compared in *c*. Interference from the fast sodium current was minimised by imposing all voltage steps from a holding potential of -50 mV. Calibration marks in *a* and *c* indicate 10 ms and current from 0 to -1 nA.

Fig. 5 (Right) Influence of the membrane potential on the conductance parameters d_{∞} , f_{∞} and τ . Activation was analysed at -50 mV; a short depolarising pulse (8 ms to -30 and -20 in *a*) activated the conductance to a degree which is proportional to the amplitude of the tail currents (arrows). Inactivation (not illustrated) was measured by imposing steps to +10 mV after 3-s pre-pulses to potentials between -70 and 0 mV. Having normalised the maximum effects to 1.0, the dimensionless variables d_{∞} and f_{∞} were plotted against the potential of the conditioning step (*b*). The inactivation time constant τ (*c*) was analysed according to Fig. 3*d*; the different symbols indicate four individual myocytes. Calibration marks indicate 4 ms and current from 0 to -1 nA.

Our data indicate that myocytes isolated from adult rat heart tissue can have electrical properties similar to those displayed by intact tissue. With regard to the slow inward calcium current, I_{si} , threshold, maximum amplitude and direction depended on membrane potential as in the intact tissue; the reversal potential is +55 mV, quite close to the values reported^{1,2}. Also, the influence of membrane potentials on the steady-state activation and inactivation curves is in good agreement with measurements on intact cardiac tissue from bovine or feline hearts^{1,2}. However, our τ_i values are similar to those estimated by us from currents recorded in rat heart ventricular trabeculae^{14,15}, that is, fast inactivation seems to be a peculiarity of the rat heart. This conclusion is supported by preliminary experiments with myocytes isolated from bovine heart tissue which revealed τ_i values of the order of 100 ms. We conclude that the glycocalyx, which is removed by the cell isolation procedure, is unlikely to be the structure originating or controlling the slow inward calcium current.

We thank Dr T. F. McDonald for his help in preparing the manuscript, and Ms M. Honecker and Ms H. Krempel for technical assistance. This work was supported by the Deutsche Forschungsgemeinschaft, SFB 38 G 2.

Low intracellular pH and chemical agents slow inactivation gating in sodium channels of muscle

Wolfgang Nonner, Bruce C. Spalding* & Bertil Hille

Department of Physiology and Biophysics, University of Washington, SJ-40, Seattle, Washington 98195

Excitation of nerve or muscle requires an orderly opening and closing of molecular pores, the ionic channels, in the plasma membrane. During the action potential, Na channels are opened (activated) by the advancing wave of depolarisation, contributing a pulse of inward sodium current, and then are closed again (inactivated) by the continued depolarisation¹. As one approach both to obtaining molecular information on the Na channel and towards further defining the recently discovered kinetic interactions of the inactivation and activation gating steps^{2–4}, we have surveyed here the effects of chemical agents reported to slow or prevent Na channel inactivation. We find that many of the agents studied by others^{5–14} on invertebrate giant axons or vertebrate nerve act on our frog skeletal muscle preparation. In addition, we have discovered that simply lowering the intracellular pH nearly eliminates inactivation. The activation mechanism seems to resist modification.

Figures 1 and 2 show examples of a loss of inactivation gating following chemical treatments. The traces are families of sodium currents recorded from a cut piece of frog semitendinosus muscle fibre under voltage clamp by the Vaseline-gap technique¹⁵. The membrane was hyperpolarised for 56 ms and then depolarised to test potentials ranging from –90 to +70 mV in 16-mV intervals. In a normal muscle fibre bathed in Ringer's solution at pH 7 (Fig. 1a) or at pH 5 (Fig. 1e), the sodium currents have a transient time course, activating quickly and inactivating fully (at least 98%) during each 8-ms depolarising test pulse. However, after a 10-min exposure to 0.7 mM *N*-bromoacetamide (NBA) in the external medium (Fig. 1b), the inactivation process is modified, and sodium currents are still large at the end of 8 ms. Sodium channels close only after the membrane potential is stepped back to the holding potential, giving a brief inward sodium 'tail current'. Even with 75-ms test pulses, the currents in NBA-treated fibres fail to inactivate

completely (Fig. 2f) and the end of the pulse is followed by a prominent tail current (not faithfully recorded at the low sampling frequency used after the first 8 ms in the record shown). Similar modifications of inactivation gating are seen in a fibre treated for 36 min with internal iodate (Figs 1c, 2b) and in fibres treated for 38 min with 40 mM external formaldehyde (Fig. 2e) or for 43 min with 1.8 mM external glutaraldehyde (Fig. 2c) followed by another 6 min in 10 mM glutaraldehyde (Fig. 2d).

These observations with frog muscle parallel the reported effects on inactivation of 20–120 mM internal iodate in frog myelinated nerve^{5,6} and of 1 mM internal (but not external) NBA in squid giant axon⁷, and they are consistent with the action-potential-prolonging effect of 2 mM external glutaraldehyde in crayfish giant axons⁸. We also tested other agents reported to act on giant axons and obtained the results listed in the last two columns of Table 1. These agents seemed uniformly less promising for future use in our preparation, but most did slow the time course of inactivation.

In one series of experiments with fibres bathed in external solutions at pH 5, we found that inactivation remained normal when the buffer was 17 mM histidine (Fig. 1e) but became incomplete during 45 min when the pH 5 buffer was 28 mM acetate (Fig. 1f). This change could be slowly reversed, especially at an intermediate stage, by returning to low-pH histidine or to normal Ringer. On the hypothesis that acetic acid might cross the sarcolemma and act by acidifying the myoplasm, we tested the effect of lowering internal pH by placing 48–60 mM biphthalate buffer at one cut end of fibres bathed externally with flowing, well buffered solutions at neutral pH. Inactivation was nearly completely lost after 50 min with pH 4 buffer at one end and after 100 min with pH 5 buffer (Figs 1d, 2h). This treatment gave the most complete removal of inactivation of any we have tried and resulted in no loss of peak current. The effect could be further potentiated by external application of pH 5, acetate-buffered Ringer.

We also examined whether bisulphite ion, which has been reported to modify endplate channels¹⁶, also modifies gating in Na channels. When 25 mM bisulphite was applied for 100 min from inside or outside in a pH range of 6 to 9, there was no effect except a gradual reduction of current. However, if one cut end of the fibre was bathed for about 1 h in a pH 5.6 bisulphite solution and then the membrane was perfused externally with a pH 5.2 bisulphite Ringer's solution, inactivation was lost (Fig. 2g), and returned slowly after both bisulphite solutions had been washed away. We believe that external bisulphite acts here simply by accelerating the acidification of the myoplasm, perhaps by diffusion of the uncharged SO₂ species. Such synergism could be

* Present address: Department of Physiology, University of Rochester, Rochester, New York 14642.

Fig. 1 Families of Na currents after treatments with agents that modify inactivation. Family *a* was recorded before, and family *b* at 8 min after, a 10-min exposure to 0.72 mM external NBA (in Ringer's buffered at pH 7 with 8 mM phosphate; internal solution: 60 mM KF, 60 mM CsF); fibre 6/19. Family *c* was obtained from fibre 6/20, at 14 min after the end of a 22-min internal application of iodate (60 mM NaIO₃, 60 mM CsF, then replaced by 20 mM Na phosphate buffer, pH 7, 100 mM CsF; external solution: Ringer's). The first 250 μ s of the tail current were not recorded. Records *d*, from fibre 6/6, were made at 103 min after the beginning of an internal treatment with pH 5, biphthalate buffer (48 mM K biphthalate, 24 mM NaOH, 60 mM CsF; outside: Ringer's). Family *e* was taken after 8 min in external Ringer's with 17 mM histidine buffer at pH 5; *f* was recorded later from the same fibre, 6/4/1, after a repeated, external application (total duration 42.5 min) of Ringer's with 48 mM acetate buffer at pH 5.1 (internal solution: 20 mM Na phosphate at pH 7, 100 mM CsF). Holding potentials -90 mV (*a-d*) or -74 mV (*e, f*); 8-ms depolarising pulses from -74 to +70 mV at intervals of 16 mV. Temperature 10-11 °C. Each record was scaled for the same amplitude of the largest inward (*a-d*) or outward (*e, f*) current; amplitudes were (*a-f*): 2.69, 0.93, 2.57, 4.64, 1.02, 0.272 μ A. The largest control currents for *c* and *d* were 3.86 and 5.55 μ A.

expected from all agents that can permeate to the myoplasm and there, by dissociation or other chemical reactions, generate free protons. In the test tube we found that added NBA, formaldehyde, glutaraldehyde or bisulphite lowers the pH of a histidine buffer solution within a few minutes from pH 7 to values lower than 4 by chemical reactions. We therefore cannot exclude the possibility that a slowly developing reduction of intracellular pH also contributes to the efficacy of these agents in muscle fibres.

Where do the chemical modifiers act? Two of the treatments we tried, iodate and low pH, were effective only from the inside of the membrane. External iodate up to 120 mM was totally without effect and low external pH gave only the known small effects¹⁷ seen in Fig. 1*e*. Other small, uncharged agents such as NBA and aldehydes were effective when applied outside, but as they can readily diffuse across membranes, they might also be acting inside. The chemical specificity of the agents we have tried has been discussed extensively elsewhere, and other

Fig. 2 Slowed Na inactivation seen with long step depolarisations. *a*, Records from a normal fibre, 6/20 (Ringer's outside; 60 mM NaF, 60 mM CsF inside). *b* Is the same fibre 16 min after the end of a 22-min internal exposure to iodate (same fibre as Fig. 1*c*). *c* Is taken from fibre 4/26 after 43 min external treatment with glutaraldehyde (1.8 mM in Ringer's; inside: 120 mM CsF), and *d* from the same fibre after a further 6 min exposure to 10 mM glutaraldehyde in Ringer's. Records *e* were taken from fibre 4/25 after 38 min external application of 40 mM formaldehyde (with 0.04% methanol) in Ringer's (inside: 120 mM CsF). Family *f* was recorded

17 min after the end of a 10-min external exposure to 0.72 mM NBA (same fibre as in Fig. 1*a, b*). *g* Is from fibre 4/20, which was treated for 72 min with internal bisulphite (19 mM NaHSO₃ in 120 mM CsF, pH 5.6), simultaneously exposed for 5 min (at 46-51 min) to external bisulphite (30 mM NaHSO₃) in Ringer's, pH 5.2, and then washed for 21 min with Ringer's. Records *h* were taken after 110 min of internal exposure to pH 5 biphthalate buffer (same fibre as in Fig. 1*d*). Same depolarisations as in Fig. 1. Temperature 10-11 °C. Currents were scaled to the same size; the maximum inward currents were (*a-h*): 3.85, 2.32, 0.51, 0.29, 0.63, 0.89, 1.99, 4.63 μ A; corresponding control currents were (*c-h*): 0.99, 0.99, 1.70, 2.69, 1.77, 4.64 μ A.

Table 1 Other experiments on frog muscle with agents reported to modify Na inactivation

Agent	Ref.	Modes of application	Our experiments	
			Depression of Na current*	Action on inactivation†
<i>N</i> -Bromosuccinimide (NBS)	7, 9	External, 1–2 mM	+	++
2, 4, 6-Trinitrobenzene sulphonic acid (TNBS)	10	External, 3–30 mM Internal, 60–120 mM (pH 7 or 9)	+	–
			++	+
4-Acetamido-4-isothiocyano-stilbene-2,2'-disulphonic acid (SITS)	10	External, 1–4.4 mM Internal, 11.5 mM	+	–
			++	+
Isethionylacetamide hydrochloride (IAH)	10	External, 3–10 mM Internal, 10–70 mM	–	–
			–	–
Glyoxal	11	External, 6–60 mM Internal, 11–60 mM	–	–
			–	+
Tannic acid	8	External, 2.2 mM Internal, 0.3 mM	++	–
			–	–
Picric acid (TNP)	13	External, 2.2 mM	++	+
High internal pH	14	Internal, pH 9.5–10	++	–

* Current depressed by less (+) or more (++) than one half.

† Inactivation slowed, but almost complete after 8 ms (+), or markedly incomplete after 8 ms (++).

authors^{7,10,11,14,18} have argued that modifications at tyrosine and arginine and reaction with lysyl- or N-terminal amino groups on the axoplasmic side of the membrane all remove Na inactivation.

Although inactivation gating was strongly modified by chemical treatments, activation gating seemed hardly affected. Figure 3 shows the voltage dependence of peak Na permeability and of the half-rise and half-fall times of the Na current during the test pulse. The normalised permeability-voltage curves are quite similar before (solid line) and after (dashed line) the chemical treatments except that with NBA, iodate and biphthalate (Fig. 3a, c, d) there is a small (<8 mV) shift to the left along the voltage axis. The half-rise times (triangles) are similarly

unchanged with NBA, formaldehyde and iodate (Fig. 3a–c), but are longer with the low internal pH (biphthalate, Fig. 3d). As is already clear, the fall times (circles) are greatly increased after all treatments, with low internal pH being the most potent.

These experiments confirm that inactivation and activation gating processes may be dissociated functionally, as if they are subserved by different parts of the channel. Perhaps the activation machinery is physically more deeply buried in the membrane and therefore less susceptible to chemical modification¹⁹. However, it must be remembered that all treatments except low internal pH also reduced the peak Na currents, and in some of these cases the reduction might reflect alterations in parts of the channel associated with activation.

Fig. 3 Effects of agents on parameters of Na current. Upper: peak permeability, calculated from the Goldman flux equation²⁰; lower: half-times for rise and fall of Na current. Δ , Time to rise to half of peak value; \circ , time after peak to fall half-way to value at 75 ms. Controls are connected by solid lines and modified parameters by dashed lines; abscissa is the voltage of the test pulse. *a*, Before and after treatment with 0.72 mM external NBA (fibre 6/19, see Figs 1a, b, 2f). *b*, Before and during treatment with 40 mM external formaldehyde (fibre 4/25, see Fig. 2e). *c*, Before and after treatment with 60 mM internal iodate (fibre 6/20; Figs 1c, 2a, b). *d*, Before and during internal exposure to pH 5, biphthalate buffer (fibre 6/6; Figs 1d, 2h). Temperature 10–11 °C.

The chemical separability does not, however, exclude the possibility of interactions between the gating processes in normal channels: activation gates may still operate differently in inactivated and non-inactivated channels²⁻⁴.

Distribution of membrane anionic sites on B16 melanoma variants with differing lung colonising potential

A. Raz, C. Bucana, W. McLellan & I. J. Fidler

Cancer Metastasis and Treatment Laboratory, NCI Frederick Cancer Research Center, PO Box B, Frederick, Maryland 21701

The interaction of metastatic cells with their environment is mediated to a large extent by the cell surface¹⁻⁵. Although several biochemical differences between tumour cells with low or high metastatic potentials have been reported⁶⁻¹⁰, the specific surface characteristics associated with metastasis have not yet been identified. One distinctive feature of murine B16 melanoma variants with low (B16-F1, B16-F10^{Lr}) or high (B16-F10) lung colonisation potentials^{11,12} is their propensity to aggregate *in vitro* with other tumour cells (homotypic clumping)^{13,14}, or with host cells (heterotypic clumping)^{15,16}. The initial sites for membrane-membrane recognition, contact and subsequent interaction are thought to be associated with dense membrane anionic sites¹⁷⁻²⁰. In the experiments reported here we determined that the distribution of cell-surface dense anionic sites, examined ultrastructurally with the use of cationised ferritin (CF), is correlated with tumour cell aggregation *in vitro* and/or production of pulmonary tumour colonies following intravenous (i.v.) injection into syngeneic recipients.

The B16-F1 (parent, intermediate metastatic potential), B16-F10 (selected *in vivo*, high metastatic potential)¹¹ and B16-F10^{Lr} (selected *in vitro* for resistance to lysis by syngeneic lymphocytes, low metastatic potential)¹² were maintained *in vitro* as described previously¹². Cells from semiconfluent monolayer cultures were collected with a short (2 min) treatment of 2 mM EDTA in Ca²⁺- and Mg²⁺-free phosphate buffer saline (PBS), pH 7.2. The cells were washed in PBS and pipetted gently to dissociate any cell clumps. In all experiments, only cell suspensions of >90% viability, as measured by trypan blue exclusion, that were free of cell aggregates were used for *in vivo* or *in vitro* studies.

The biological behaviour *in vivo* of the cell lines was evaluated by i.v. injection of 5 × 10⁴ viable cells into groups of 10 mice

Fig. 1 Distribution of cationised ferritin on the cell surface of B16 melanoma cell lines: *a*, B16-F1; *b*, B16-F10; and *c*, B16-F10^{Lr}. Cell suspensions were fixed with 2.5% glutaraldehyde in Na-Veronal buffer (pH 7.4) for 60 min at 24 °C. Following washing three times with the same buffer the fixed cells were incubated for 3 min with 0.33 mg ml⁻¹ cationised ferritin (Miles Yeda)¹⁴. The unbound cationised ferritin was washed away and the cells were post-fixed with 1% buffered OsO₄ for 60 min at 24 °C and stained *en bloc* with a solution of 1% uranyl acetate. The cells were dehydrated with a graded series of ethanol followed by propylene oxide and embedded in Emix resin (Ted Pella, Inc.). Thin sections were obtained with an LKB ultramicrotome and analysed with the aid of Hitachi HU-12A electron microscope at an operating voltage of 75 kV. Serial sections of 600 Å through the CF clusters established that the observation was not due to an artefact of sectioning.

Table 1 Distribution of cationised ferritin clusters on surface of B16 melanoma cells

Cell lines	No. of cells with CF clusters/ no. of cells examined	Per cent of total
F1	38/180	21
F10	114/279	41
F10 ^{Lr}	51/180	28
F10*	27/122	22

Methods as described in Fig. 1. The results represent the average obtained from a random cell thin sections, and blind scoring. The experiments were repeated twice with cells grown from different (frozen) stock cultures with similar results.

* B16-F10 cell suspensions (1 × 10⁶ cells ml⁻¹) in 5% FCS in medium were placed in a 15-ml conical tube and rotated gently for 60 min at 37 °C. The aggregates were then allowed to sediment for 30 min at 24 °C. The upper third layer of the suspension was collected, washed with PBS, fixed and stained with CF.

Table 2 Homotypic aggregation of B16 melanoma cell lines

Cell line	Per cent cells in aggregates
F1	32
F10	52
F10 ^{Lr}	11
F10*	25

B16 melanoma cell suspension (1×10^6 cell ml⁻¹) in medium containing 5% FCS were placed into a 15-ml conical tube and rotated gently for 60 min at 37°C. An aliquot from each suspension was placed into a haemocytometer and the number of single cells per field was determined. The percentage of aggregates was calculated from the cell number in control experiments where the cells were incubated at 4°C.

* B16-F10 cell suspension was incubated for 30 min with 0.5 µm ml⁻¹ of neuraminidase, then washed and allowed to aggregate as above.

each. The mice were killed 21 days later and the number of tumour colonies in the lungs was determined. The median number of metastases produced by B16-F1, B16-F10 and B16-F10^{Lr} cells was 12, 130 and 2, respectively. These results agree with earlier reports^{6-8,11,12}. Quantitative determination of both intracellular and extracellular sialic acid²¹, demonstrated no differences among the three B16 lines as each line contained about 0.025 µmol of sialic acid per 10⁶ cells.

The distribution (topography) of the cell-surface anionic sites was examined by electron microscopy of cells treated with CF as described previously²². To avoid a possible artefact of clustering of the ligand on live cells²³, we examined the distribution of CF on glutaraldehyde prefixed cells. Striking differences in ferritin binding on the surface of the B16-F10 (high metastasis) and B16-F1 and B16-F10^{Lr} (low metastasis) were observed (Fig. 1, Table 1). Specifically, in over 70% of the B16-F1 and B16-F10^{Lr} cells the CF was bound to the cell surface as a continuous discrete layer where each CF particle was separated from an adjacent particle by ~100 Å. In contrast, in 41% of the B16-F10 cells the ferritin particles were clustered on the plasma membrane (Table 1). In only 21% of B16-F1 and 28% of B16-F10^{Lr} cells, were small clusters of CF particles found.

The frequency at which the cells in the population demonstrated dense cell-surface anionic sites correlates with the degree of *in vitro* homotypic aggregation (Table 2). In this system at least, homotypic aggregation *in vitro* is energy and fetal calf serum dependent, as at low temperatures (4°C) or in absence of serum no significant aggregation of B16 cells could be detected. Neuraminidase treatment (0.5 units ml⁻¹, 30 min at 37°C) of B16-F10 melanoma cells before the homotypic aggregation assay reduced the number of cells per aggregate (Table 2).

Not all cells in the B16-F10 suspension participate in the process of homotypic aggregation. The frequency of dense anionic sites among single (unaggregated) B16-F10 cells was

Table 3 Incidence of pulmonary metastases in C57BL/6 mice following the i.v. injection of B16-F10 melanoma cells

Source of B16-F10 cells	Median (range)* of pulmonary metastases
1. Control, total population†	63.5 (37-96)
2. Single cells recovered from aggregates‡	66 (14-146)
3. Single cells recovered from supernate§	29 (1-100), P < 0.001

* Ten mice per group were injected with 5×10^4 viable cells (>90%) in 0.2 ml of PBS. Pulmonary metastases were counted with a dissecting microscope 18 d after i.v. injection.

† B16-F10 cells were incubated in CMEM and 5% FCS for 60 min at 4°C and then washed with PBS.

‡ B16-F10 aggregates (Table 2) were sedimented and dissociated by gentle pipetting. The cells were washed in PBS.

§ Single cells obtained from upper third layer on the suspension (unaggregated cells).

|| Statistically significant group 3 versus 2 or 1.

remarkably similar (22%) to that observed in the B16-F1 and B16-F10^{Lr} suspensions. Evaluations of CF clusters on the surfaces of the cells within the aggregate could not be accomplished as the CF molecules did not penetrate the aggregates. In the final experiments we injected syngeneic mice i.v. with single cell suspensions consisting of B16-F10 cells (viability of >90%) from: the starting (unaggregated) population; those recovered from clumps; or those that did not participate in the aggregation process. The data of a representative experiment demonstrate that B16-F10 cells that did not participate in the homotypic aggregation process *in vitro* formed fewer pulmonary lung colonies than did single B16-F10 cells recovered from cell aggregates (Table 3).

In conclusion, we found no quantitative differences in total cellular sialic acid among three cell lines of the B16 melanoma with different metastatic propensities. In contrast, differences in the topography and display of dense anionic sites were detected among the lines. The visualisation of cell-surface dense anionic sites may be a useful tool for the investigation of subtle changes in the cell surface of metastatic cells. Such changes might account for the differences in the propensity of the B16 melanoma cells to form experimental pulmonary tumour colonies.

Peanut lectin binding properties of germinal centres of mouse lymphoid tissue

M. L. Rose, M. S. C. Birbeck, V. J. Wallis, J. A. Forrester & A. J. S. Davies

Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, Fulham Road, London SW3 6JB, UK

Peanut (*Arachis hypogaea*) lectin (PNL) has been shown to agglutinate the 90% of cells from murine thymus which are supposed to be immature cortical thymocytes¹. Further studies on the numbers of thymocytes binding fluorescein isothiocyanate conjugated PNL (FITC-PNL) confirmed the large proportion of PNL binding cells^{2,3}. In other organs such as bone marrow, spleen and peripheral lymph nodes, smaller proportions of PNL positive cells have been recorded^{2,3}. PNL-positive cells outside the thymus have been reported to be either Th1-positive or null cells^{2,3}. It has also been suggested that PNL

binding may be a marker for immaturity not only in relation to T lymphocytes² but also amongst haematopoietic stem cells⁴. Thus PNL binding as an aspect of lymphocyte differentiation is a matter of considerable interest. The current study describes the distribution of horseradish peroxidase-conjugated PNL (HRP-PNL) on frozen sections of mouse lymphoid organs. It seems that PNL binds to cells in germinal centres but not to those in some other areas containing activated lymphocytes. There is good correlation between the presence of PNL-binding germinal centres in frozen sections of lymphoid organs and the number of PNL-binding cells counted in cell suspensions from the same organs.

In 8–12-week-old male CBA mice the proportions of lymphocytes which were able to bind FITC-PNL in cell suspensions from thymus, spleen, peripheral lymph nodes and bone marrow (Table 1) were found to be similar to those previously reported^{2,3}. However, the observation that 20% or more of Peyer's patch lymphocytes bind PNL led to the investigation of the localisation of the PNL-binding cells in Peyer's patches using frozen sections stained with HRP-PNL (Fig. 1a). It can be seen that there is a close correlation between the PNL-binding area and the germinal centre which can be observed in sections conventionally stained with haematoxylin and eosin (H&E) (Fig. 1b). Comparable results were obtained using FITC-PNL or H&E on frozen sections of rat Peyer's patches. Peripheral lymph nodes which in unstimulated laboratory mice usually lack germinal centres, did not stain with HRP-PNL but the few germinal centres to be found in spleen from unstimulated mice did prove to be PNL-positive. So far all germinal centres have bound PNL but it should be stressed that much more material must be examined before any great weight can be put on this finding. PNL binds to terminal galactosyl residues with the highest affinity for the sequence β -D-galactose-(1 \rightarrow 3)D-N-acetylgalactosamine⁹. The binding of PNL to germinal centres was completely abrogated in the presence of 0.1M galactose but not 0.1M glucose or mannose. Thus the binding of PNL to germinal centre cells is probably to terminal galactose residues on the cell surface.

Germinal centres contain dividing cells and their lymphocytes are pyronin-positive, indicating a higher degree of metabolic activity than is present in resting lymphocytes¹⁰. It was therefore of interest to determine whether PNL would bind to other activated lymphocyte populations. Local stimulation with the

Fig. 1 Binding of HRP-PNL on frozen sections of murine Peyer's patches (a) and section from the same block conventionally stained with H & E (b). Peanut lectin was prepared according to Table 1 legend. HRP-PNL conjugate was prepared according to the method of Nakane⁸. Frozen sections (4- μ m thick) of mouse Peyer's patch were air dried, and stained with HRP-PNL (20 μ g PNL per ml) for 30 min at room temperature. Sections were washed three times in PBS and staining was developed using 3, 4, 3', 4'-tetra-aminobiphenyl hydrochloride. Sections were washed again in PBS, dehydrated and mounted. Magnification $\times 105$.

Table 1 Percentage of FITC-PNL binding cells in lymphoid organs of unstimulated CBA mice

Expt no.	1	2	3
Peripheral lymph node	4.0	3.0	
Spleen	6.0	5.0	
Thymus	76.0	82.7	88.0
Bone marrow	4.0		
Peyer's patch	26.7	26.0	19.4

Peanut lectin was prepared according to the method of Lotan *et al.*⁵, with the major exception that the final affinity purification step was performed using a column of lactose bound to epoxy activated Sepharose 6B from which the lectin was displaced by 50 mM galactose. The preparation possessed haemagglutinating activity of 31,000 units per mg towards neuraminidase-treated human erythrocytes, and showed only one protein band on disc electrophoresis at pH 8.6. PNL was conjugated to FITC⁶ in the presence of galactose to produce a FITC/PNL molar ratio of 2.7. Cell suspensions were prepared as previously described⁷ and 100 μ l of cells at 10^7 per ml in PBS containing 0.05% sodium azide were mixed with 100 μ l FITC-PNL (50 μ g PNL per ml) in phosphate-buffered saline (PBS) containing azide. After 30 min incubation at 37°, the cells were washed three times and resuspended in 100 μ l of PBS containing azide. Cells were examined under fluorescence optics using a Zeiss epifluorescence condenser IV/F on standard 18 microscope. Only viable cells (distinguishable from dead cells under phase contrast) with strong membrane fluorescence were scored as positive. In each experiment (done on different days) the relevant organs from at least four mice were pooled, tubes were counted in duplicate and the mean is shown. 200 cells per tube were scored.

contact sensitising agent, oxazolone, results in intense T-cell proliferation in the paracortex of the draining lymph nodes at 3 days¹¹. Frozen sections of such nodes did not bind PNL to an enhanced degree nor was it possible to detect an increase in the numbers of PNL-binding cells in cell suspensions from lymph nodes activated in such a manner (Table 2). However, at later times (days 7–15) increased numbers of PNL-binding cells were observed (Table 2). This increase was correlated with the time of appearance of germinal centres. No increase in the numbers of PNL-binding cells was found in spleen cells which had been activated *in vitro* with either lipopolysaccharide or with phytohaemagglutinin (Table 3). Thus PNL does not bind to activated lymphocytes *per se* but only to cells in particular anatomical locations. The fact that PNL-binding cells can be recovered from unfixed cell suspensions and demonstrated by agglutination¹ suggests that PNL is membrane binding.

Table 2 Percentage of FITC-PNL binding cells in the axillary lymph nodes of mice stimulated with oxazolone

	Days after oxazolone	No. of mice	Mean
Expt 1	0	3	4.0 ± 0.6
	3	4	3.4 ± 1.5
	7	2	12.3 ± 1.0
	13	1	13.9
	17	1	7.4
Expt 2	0	4	2.8 ± 1.2
	4	4	3.3 ± 0.9
	11	4	15.3 ± 3.4
	15	4	19.2 ± 6.0

PNL and FITC-PNL were prepared as described in the legend to Table 1. Mice were painted on the shaved flanks with 3 mg of 4-ethoxymethylene-2-phenyl-oxazolone (oxazolone, BDH) dissolved in 100 µl of ethanol. At various times after immunisation, mice were killed and cell suspensions from the draining axillary lymph nodes were prepared, they were washed twice and resuspended at a concentration of 10^7 per ml in PBS containing 0.05% sodium azide. The number of FITC-PNL binding cells was estimated as described in Table 1. Results are the mean ± s.d. from individual mice.

Table 3 Percentage of FITC-PNL binding cells in spleen cultured with LPS or PHA

	24	48	72
LPS	4.9 ± 1.6	4.2 ± 1.3	2.8 ± 1.0
PHA	4.9 ± 0.8	5.3 ± 3.4	4.8 ± 3.0

Spleen cells were cultured in RPMI1640 containing 10% fetal calf serum, 300 mM glutamine, 200 unit ml⁻¹ penicillin and 150 µg ml⁻¹ streptomycin, in 1 ml cultures at a concentration of 2×10^6 cells per ml with phytohaemagglutinin (PHA, Wellcome, 2.5 µg ml⁻¹) or 4×10^6 cells per ml with lipopolysaccharide (LPS) from *Escherichia coli* 055:B5 (Difco, 50 µg ml⁻¹). After culturing (at 37 °C in an atmosphere of 7% CO₂, 10% O₂, 83% N₂) for 24, 48 or 72 h, cells were collected and the numbers of FITC-PNL binding cells were estimated as described in Table 1. Results are the mean ± s.d. from four replicate cultures. Control cell suspensions of uncultured spleen revealed 6.0 ± 2.0, 5.5 ± 1.7 and 4.7 ± 1.1% FITC-PNL binding cells at 24, 48 and 72 h respectively. A control thymocyte suspension done at 72 h revealed 82% PNL binding cells.

The origin of cells in germinal centres has not been fully determined. Weissman¹² has shown that there are some T cells present by the use of fluorescinated anti-T cell antiserum. However, neither the numbers nor the pattern of dispersion of these cells corresponds to that seen with PNL. Thus the PNL-positive cells are unlikely to be mainly T lymphocytes. In the same study Weissman demonstrated that a substantial proportion of the area of germinal centres was immunoglobulin positive. This finding must be viewed with some caution before it is assumed that many or all of the cells in germinal centres are surface immunoglobulin-positive B lymphocytes. It is known that, in at least some germinal centres, there are dendritic reticular cells which bind antigen-antibody complexes and which have cell membranes with vast processes on which the complexes are to be found¹³. Preliminary studies in this laboratory with double staining techniques on cell suspensions from Peyer's patches have shown that some of the PNL-positive cells appear to be surface immunoglobulin positive, whereas others are not obviously so. Thus the anatomic origins of PNL-positive germinal centre cells are not clear, although it seems likely that some or all of them are B lymphocytes.

It is an intriguing coincidence that cortical thymocytes and germinal centre cells bind PNL. These observations, together with Reisner's suggestion⁴ that PNL binding is a marker of immaturity among T cells and cells of the haematopoietic stem cell population, again raise the possibility that germinal centres harbour a population of immature B cells^{14,15}. Use of PNL to separate germinal centre cells should allow their properties and functions to be characterised further.

We thank Geoff Parnell, Dave Robertson and Nick Bradley for technical assistance. This work was supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the MRC and the Cancer Research Campaign.

Protective monoclonal antibodies recognising stage-specific merozoite antigens of a rodent malaria parasite

Robert R. Freeman, Avril J. Trejdosiewicz & George A. M. Cross

Department of Immunochemistry, The Wellcome Research Laboratories, Langley Court, Beckenham, Kent BR3 3BS, UK

Immunity to malaria is mediated, at least in part, by antibody. Resistance to infection has been passively transferred with immune serum or its immunoglobulin fraction in human¹, simian² and rodent^{3,4} malaria. However, because of the structural and antigenic complexity of the malaria parasites^{5,6}, it has proved difficult to identify and characterise those parasite antigens against which protective antibody is directed. We have produced several hybrid cell lines secreting monoclonal antibodies against the rodent malaria parasite, *Plasmodium yoelii*, and we now report that, of the antibodies tested, only those specific for antigens exclusive to the merozoite were protective in passive transfer experiments. Other anti-*P. yoelii* monoclonal antibodies, apparently recognising antigens in the membrane of the infected erythrocyte, were not protective on passive transfer. The protective monoclonal antibodies should be useful in the isolation of the important antigens of this parasite.

Spleen cells from two *P. yoelii*-immune BALB/c mice were fused with P3-NS1/1-Ag4-1 myeloma cells in the presence of polyethylene glycol⁷. The cells were dispensed into 144 tissue culture wells in 2-ml volumes of hypoxanthine-aminopterin-thymidine-selective medium⁸, using RPMI-1640 medium supplemented with 10% fetal calf serum as a base⁹. After 10 days, the culture supernatants were tested for *P. yoelii*-specific antibody by indirect immunofluorescence (IIF). Of 143 cultures tested, 38 were positive, 20 producing antibody apparently directed against the infected erythrocyte membrane and 18 producing antibody against the parasite itself. From the initial screening, five distinct IIF specificities were detected. Cultures representative of each of the IIF specificities were expanded in selective medium without aminopterin, and hybridoma lines were subsequently cloned in semi-solid agar overlaid with medium.

Fig. 1 IIF staining reactions produced by: *a*, whole anti-*P. yoelii* immune serum diluted 1 in 1,000, and *b-f*, 1 in 10,000 dilutions of sera from mice carrying ascites tumours derived from cloned hybridoma cell lines: *b*, WIC 25.1; *c*, WIC 25.23; *d*, WIC 25.37; *e*, WIC 25.54; *f*, WIC 25.77. Supernatants from cultures of these lines produced IIF reactions identical to those produced by the sera. To produce monoclonal antibodies, 2×10^8 spleen cells from BALB/c mice recovered from mild *P. yoelii* 17X infection and rechallenged three times with virulent *P. yoelii* (YM strain) were mixed for fusion with 2×10^7 P3-NS1/1-Ag4-1 myeloma cells⁹. To prepare antigen for the IIF test, BALB/c mice were infected with virulent *P. yoelii* 24 h before subcutaneous injection with cyclophosphamide (200 mg per kg). After 4 days, when parasitaemia was >60%, infected blood was enriched for schizonts by centrifugation through isopaque/Ficoll¹² (2,000g for 20 min at 20 °C). The enriched upper layer of cells was washed in phosphate-buffered saline (PBS), diluted 1 in 100 in PBS, and applied dropwise to glass slides. The antigen preparation was allowed to dry at room temperature, then slides were stored at -20 °C. Giemsa staining of preparations showed that all red cells were parasitised (30% schizonts, 70% trophozoites approximately). Free merozoites were also observed. The procedure for the IIF test has been described elsewhere¹³; in the present study, background fluorescence was minimised by using immunoabsorbant-purified rabbit anti-mouse Ig. ($\times 180$).

The five cloned lines secreted antibodies covering the range of IIF specificities originally detected. Whereas polyspecific serum from immune mice produced a generalised staining of *P. yoelii*-infected erythrocytes in the IIF assay, the monoclonal antibody specificities produced characteristic, restricted patterns of fluorescence (Fig. 1). Thus, with specificity 25.1, the membranes of a subpopulation of infected erythrocytes fluoresced, whereas specificity 25.54 bound to the membranes of all infected erythrocytes with a distinct patchy staining pattern. Specificity 25.23 bound to an antigen common to all developmental stages of the blood form of the parasite. Specificities 25.37 and 25.77 bound to antigens only present in merozoites, free and within mature schizonts. All merozoites in the antigen preparation apparently reacted with the two merozoite-specific antibodies, but the

Table 1 Characteristics of the anti-*P. yoelii* monoclonal antibodies secreted by five cloned hybridoma lines

Hybridoma line	IIF specificity of secreted antibody	IIF cross-reactivity against <i>P.v. petteri</i>	Immunoglobulin subclass
WIC 25.1	Infected erythrocytes	+	IgG2a
WIC 25.23	Trophozoites, schizonts and merozoites	+	IgG2a
WIC 25.37	Merozoites	-	IgG1
WIC 25.54	Infected erythrocytes	+	IgG3
WIC 25.77	Merozoites	+	IgG2a

IIF specificity was determined by testing against *P. yoelii*, YM strain. For immunoglobulin subclass determination, concentrated culture supernatant samples were tested by double diffusion in agar against rabbit antisera specific for the mouse immunoglobulin subclasses IgM, IgG1, IgG2a, IgG2b, IgG3 and IgA.

possibility that a minor subpopulation of merozoites failed to react could not be excluded.

The antibody products of the five lines were characterised with respect to immunoglobulin subclass by double diffusion using subclass-specific antisera. All were found to be of the IgG class (Table 1). They were also screened for cross-reaction against uninfected BALB/c erythrocytes and against a heterologous rodent malaria parasite, *Plasmodium vinckei petteri*, by IIF. None reacted with the uninfected erythrocytes but all except the merozoite-specific antibody secreted by line WIC 25.37 cross-reacted with *P.v. petteri* antigens (Table 1).

Serum pools containing high titres of anti-*P. yoelii* monoclonal antibodies were obtained from hybridoma tumour-bearing BALB/c mice (Table 2). These sera were tested in passive transfer experiments for their effect on the course of virulent *P. yoelii* infection (Fig. 2). Mice receiving monoclonal antibody specificities 25.1 and 25.54, apparently directed against infected erythrocytes, were not protected against *P. yoelii*. Neither was protection transferred with serum containing a high titre of specificity 25.23, directed against an antigen common to all developmental stages of the asexual erythrocytic parasite (trophozoites, schizonts and merozoites). However, transfer of sera containing the antibodies specific for late-appearing merozoite antigens, specificities 25.37 and 25.77, resulted in inhibition of *P. yoelii* parasitaemia, and none of these mice died. Whole immune serum was even more effective, causing the elimination of patent parasitaemia within 48 h of transfer. The protective activity of the monoclonal antibodies was not restricted to one IgG subclass, as specificity 25.37 was an IgG1 and specificity 25.77 was an IgG2a.

The eventual recovery of those groups treated with monoclonal anti-merozoite antibody was probably not mediated by the transferred serum, but rather by the recipients' immune

Fig. 2 The course of *P. yoelii* infection in groups of five BALB/c mice injected intraperitoneally with 0.5 ml of normal mouse serum (○), *P. yoelii*-hyperimmune serum (●), or serum from mice carrying tumours derived from cloned hybridoma lines: WIC 25.1 (△), WIC 25.23 (□), WIC 25.37 (▲), WIC 25.54 (▽) and WIC 25.77 (■). Serum was transferred when parasitaemia had reached 0.01–0.1%. Mean survival times are indicated (d). The vertical bars indicate standard deviations.

response. The direct effect of the transferred antibody was seen during the week following transfer, when the normally fulminating *P. yoelii* YM infection was retarded, following a course more typical of self-limiting *P. yoelii* 17X infection.

Inhibition of red cell invasion by merozoites may involve the blocking by antibody of receptor determinants on the merozoite surface. A polyspecific antiserum would be expected to be more efficient in receptor blocking than a monospecific antiserum. This may explain the greater degree of protection transferred with whole hyperimmune serum than with serum containing a single anti-merozoite specificity. An interesting alternative possibility is that the delayed parasitaemia observed in mice treated with specificities 25.37 and 25.77 was due to the emergence of a population of merozoites not reacting with these antibodies.

It is not known whether monoclonal specificities 25.37 and 25.77 recognise distinct merozoite antigens or different determinants on the same antigen. They give similar IIF staining reactions against *P. yoelii* (Fig. 1), but the observation that specificity 25.77 is cross-reactive with *P. v. petteri* indicates that this antibody possesses a binding specificity distinct from that of the other protective monoclonal antibody species. Using monoclonal antibodies and immunoprecipitation, we are now in the process of identifying the parasite antigens involved.

Our findings do not support the view that antibodies specific or parasite antigens present in the membrane of the infected erythrocyte are protective¹⁰, although they do indicate the presence of at least one erythrocyte membrane-localised *P. yoelii* antigen, against which a substantial but apparently non-protective antibody response is made in the immune host. However, we have tested only two membrane-specific monoclonal antibodies, and our results do not rule out the possibility

that other membrane-specific antibodies may prove protective. Furthermore, although specificities 25.1 and 25.54 bound to the membranes of infected erythrocytes in fixed smears, they did not bind to infected erythrocytes in suspension, and so the antigens recognised by these antibodies are probably not externally expressed on infected erythrocytes. Nevertheless, protection was transferred with the anti-merozoite monoclonal antibodies, and it therefore seems that in the case of *P. yoelii*, as with *Plasmodium knowlesi*¹¹, antibody-mediated protection against malaria acts at the level of the free merozoite, inhibiting invasion of host erythrocytes.

We thank Lynn Bushby for technical assistance, and Professor F. E. G. Cox, Dr D. Snary and Dr L. H. Miller for helpful discussions. The P3-NS1/1-Ag4-1 myeloma line was provided by Dr A. F. Williams.

Copper metallothionein, a copper-binding protein from *Neurospora crassa*

Konrad Lerch

Biochemisches Institut der Universität Zürich, Zürichbergstrasse 4, CH-8032 Zürich, Switzerland

Copper is an essential constituent of many proteins which participate in biologically important reactions¹. In contrast to iron, where different metal storage and transport proteins have been extensively characterised, the existence of copper proteins serving such functions is still a matter of controversy^{2–4}. Studies on the biosynthesis of tyrosinase from *Neurospora crassa* with respect to the copper status of this fungus have shown that this organism accumulates copper with the concomitant synthesis of a small molecular weight copper-binding protein. This protein is now shown to have a striking sequence homology to the zinc- and cadmium-containing metallothioneins from vertebrates⁵. Growth experiments suggest that this molecule fulfills several important physiological functions in this organism such as copper storage, copper detoxification and provision of copper for tyrosinase.

When *N. crassa* is grown in the presence of 0.5 mM of CuSO₄ in the culture medium most of the intracellular copper is found in a high molecular weight fraction during the logarithmic growth period (Fig. 1). However, in the stationary phase about 10% of the copper taken up by the cells accumulates in the form of a low molecular weight protein (Fig. 1). This copper-binding protein was isolated from lyophilised mycelium (obtained as described in Fig. 1 legend) by gel filtration of the crude extract on Sephadex G-50 and subsequent chromatography on DEAE-cellulose. The pure protein is composed of only seven different amino acids with a strikingly high content of cysteine (28%), serine (28%) and glycine (24%). The amino acid composition is: Asx, 2.9; Ser, 6.9; Gly, 6.0; Ala, 1.0; Cys, 6.9 (determined as carboxymethylcysteine); Lys, 1.0. The protein binds a total of 6 g atoms of copper per mw of 2,200. The copper-free apoprotein can be obtained by exposure of the holoprotein to low pH (<pH 1.0) and subsequent metal removal by gel filtration. The homogeneity of the molecule was further corroborated by the

Table 2 IIF titres of sera used in passive transfer experiments

Serum source	Anti- <i>P. yoelii</i> IIF titre
BALB/c mice carrying hybridoma WIC 25.1	1:30,000
BALB/c mice carrying hybridoma WIC 25.23	1:32,000
BALB/c mice carrying hybridoma WIC 25.37	1:128,000
BALB/c mice carrying hybridoma WIC 25.54	1:30,000
BALB/c mice carrying hybridoma WIC 25.77	1:128,000
Immune BALB/c mice*	1:70,000
Normal BALB/c mice	<1:20

Anti-*P. yoelii* IIF titre is expressed as the highest dilution giving positive fluorescence.

* Donors had recovered from mild *P. yoelii* 17X infection, and serum was taken 7 days after challenge with virulent *P. yoelii* (YM strain).

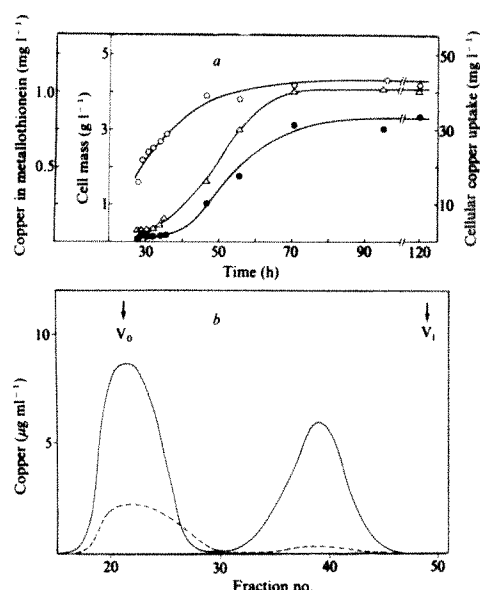

Fig. 1 *a*, Growth curve of *N. crassa* in the presence of 0.5 mM CuSO_4 in the culture medium. The amount of copper metallothionein (●), the uptake of copper from the medium (Δ) and the increase of cell mass as dry weight (○) are shown as a function of time. Cultures of 400 ml half-strength Vogel medium N (ref. 17) supplemented with 0.5 mM CuSO_4 were grown in 1-l Erlenmeyer flasks at 25 °C by shaking at 105 oscillations min^{-1} on a reciprocal shaker. Cells were collected by filtration through cheesecloth, washed with distilled water and the lyophilised mycelium extracted with 50 mM phosphate, pH 7.2. The concentration of copper metallothionein was determined by gel filtration of crude extracts on Sephadex G-50 in 10 mM Tris-HCl, pH 8.0, and subsequent measurement of the metal content of the fraction eluting at an apparent mw of about 3,000. Copper analyses were carried out by atomic absorption spectroscopy. All parameters are expressed per l of culture medium. *b*, Sephadex G-50 elution profiles of crude extracts from 35-h (---) and 70-h (—) old mycelium. Experimental details as in *a*.

determination of its primary structure using automated Edman degradation of the pyridine-ethylated apoprotein¹⁰. Partial sequence analyses of the tryptic peptides derived from the S-aminoethylated apoprotein¹¹ and amino acid analyses of tryptic peptides were in agreement with the results from the automated Edman degradations. The amino acid sequence is strikingly similar to those of the amino-terminal region of the Cd/Zn metallothioneins from man, horse and mouse¹²⁻¹⁴ (Fig. 2). The cysteinyl residues of the *Neurospora* copper-binding protein occupy exactly the same positions as the first seven cysteinyl residues in the amino-terminal sequence region of the Zn/Cd metallothioneins. In addition, serine residue 12 is invariant in all four proteins. Note the complete lack of aromatic amino acids in the copper-binding protein from *N. crassa* as well as in all the Cd/Zn metallothioneins sequenced so far⁹. Because of these common structural features we categorise the *Neurospora* copper-binding protein as a member of the superfamily of metallothioneins⁹. Further, it is suggested that the gene of the *Neurospora* copper-binding protein is related to the primordial gene of the vertebrate metallothioneins which might have evolved to the well characterised present day forms through gene duplication.

Fig. 2 Comparison of sequences of *Neurospora* copper metallothionein and Zn/Cd metallothioneins from human¹², equine¹³ and mouse¹⁴ livers. Only the amino-terminal portions of the Zn/Cd metallothioneins displaying sequence homology to the *Neurospora* copper metallothionein are shown. Identical residues are indicated by boxes.

What is the state of the copper bound in *Neurospora* metallothionein? Absorption and electron paramagnetic resonance spectroscopy of the freshly isolated protein suggest the copper to be present in the cuprous form. The lack of free cysteine residues and disulphide bridges as well as the broad featureless absorption around 250 nm are indicative of a copper(I)-thiolate binding mode. On the basis of these findings it is proposed that the model for *Neurospora* copper metallothionein is as shown in Fig. 3.

According to this model the net charge of the molecule is expected to be -1 at neutral pH, which is in line with the elution behaviour of the protein on DEAE-cellulose at pH 8.0. The structure is also supported on the grounds of model studies of Cu(I) complexes with sulphur-containing ligands¹⁵, as is the stoichiometry of ligand to metal of close to one.

What is the biological function of *Neurospora* copper metallothionein? Because copper is considered to be a rather toxic element for most organisms¹⁶ the protein could be involved in the detoxification of this metal as was discussed for metallothionein with respect to cadmium⁹. However, the large metal-binding capacity of *Neurospora* copper metallothionein also makes it a good candidate for an intracellular storage protein. This is supported by the results shown in Fig. 4*a*. The amount of copper metallothionein depends on the copper concentration up to approximately 100 μM and then levels off to reach a constant value up to 1 mM Cu in the culture medium. Above 2 mM the growth sharply declines, with a concomitant increase in free ionic copper intracellularly and a decrease in copper metallothionein.

Fig. 3 Proposed model for *Neurospora* copper metallothionein.

These results clearly point to different functions of metallothionein in the copper metabolism depending on the amount of copper present in the culture medium. The complete uptake of the metal ion at low, presumably physiological concentrations of copper and the appearance of relatively large amounts of the metal ion intracellularly in the form of metallothionein (>40% of intracellular copper) is fully consistent with a storage function. On the other hand, the pronounced tolerance towards copper within a rather broad concentration range characterised by a constant copper metallothionein content suggests a detoxification function. At very high concentrations of copper (>3 mM) in the culture medium the toxic effects predominate; this is demonstrated by a sharp increase in intracellular free ionic copper and by a marked decrease in copper metallothionein.

As *Neurospora* copper metallothionein has an exceptionally high cysteine content the relationship between the available sulphur in the culture medium and the amount of copper metallothionein was also investigated (Fig. 4*b*). The data not only demonstrate a correlation between cellular copper uptake and appearance of metallothionein as pointed out above, but also show dependence of the two parameters on the sulphate

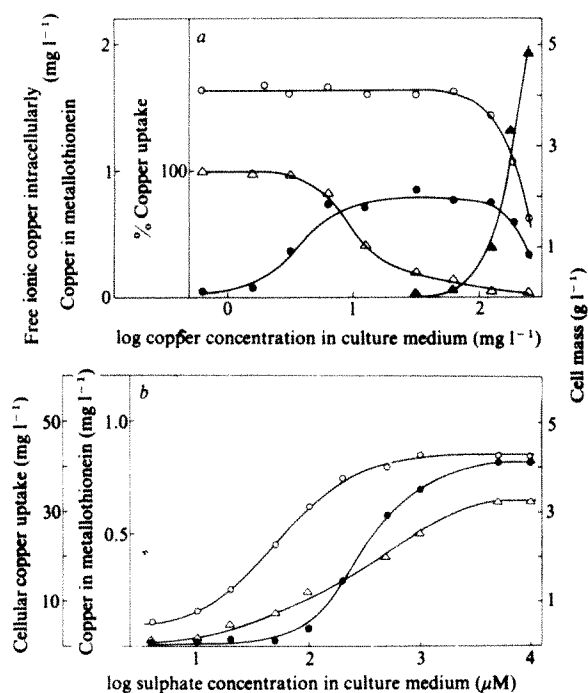

Fig. 4 *a*, The effect of copper added to the medium on the growth of *N. crassa* (○), the amount of metallothionein (●), the percentage of copper taken up from the culture medium (△) and the amount of free ionic copper (eluting at V_i on Sephadex G-50) (▲). Copper was added as $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. Cells were collected after 72 h and processed as described in Fig. 1 legend. The total amount of copper taken up by the cells was determined by atomic absorption spectroscopy on samples wet-ashed at 120 °C for 2 h with an acid mixture made from a 2:1 ratio of concentrated nitric acid to 70% perchloric acid. *b*, The effect of sulphate added to the medium on the growth of *N. crassa* (○), the amount of copper metallothionein synthesised (●), and the copper uptake from the culture medium (△). Copper was added as $\text{Cu}(\text{NO}_3)_2$ at a concentration of 0.5 mM. Sulphate was added as $(\text{NH}_4)_2\text{SO}_4$. Cells were collected after 72 h and processed as described in Fig. 1 *a* legend.

levels in the culture medium. Further, the toxic effects of the copper as manifested by the decreased growth of the fungus are clearly related to the sulphate concentration. These results once more strongly suggest a function of copper metallothionein in copper detoxification.

Finally, copper metallothionein might serve the function of a metal donor to the active sites of copper-containing enzymes. This conjecture is supported by *in vitro* reconstitution studies with *Neurospora* apotyrrosinase and copper metallothionein. The complete reconstitution of apotyrrosinase (20 μM in 0.1 M sodium phosphate, pH 7.5) with a twofold excess of Cu^{2+} ions at 0 °C is a rather slow process (5–10 h); surprisingly, the treatment of apotyrrosinase with copper metallothionein in the same conditions is faster by almost an order of magnitude. As the concentrations of intracellular free ionic copper are extremely small in physiological conditions, it is tempting to ascribe to *Neurospora* copper metallothionein an *in vivo* metal donor function.

Storage enhances chromosome damage after exposure of human leukocytes to mitomycin C

H. J. Evans & Vijayalaxmi

Medical Research Council, Clinical and Population Cytogenetics Unit, Western General Hospital, Edinburgh EH4 2XU, UK

Two of the distinctive differences between the mutagenic response of *Drosophila* sperm exposed to X rays and to alkylating agents, are: (1) an increase in the incidence of chromosomal structural changes with increasing storage time (days, or weeks) prior to fertilisation following treatments with chemical mutagens, but not X rays, and (2) the frequent occurrence of F_1 individuals mosaic for either mutation or chromosome structural change after chemical treatment, but not after X-ray radiation¹. Similar time-dependent increases in mutations and chromosome aberrations have also been reported for fungal spores² and plant seed root meristem cells³ exposed to alkylating agents, but no enhancing effect of storage could be demonstrated in confluent human fibroblasts exposed to an alkylating agent *in vitro*⁴. We show here that a storage effect can be demonstrated for sister chromatid exchange (SCE) and, to a much greater extent, for chromosome structural changes in human lymphocytes exposed to mitomycin C and stored for various periods before stimulation with phytohaemagglutinin (PHA). Moreover, mitomycin C-treated G_0 cells, which normally develop only chromatid-type aberrations, also yield chromosome-type changes after storage. This result implies a time-dependent alteration in the induced lesions following storage, and predicts a decreasing incidence of mosaicism with increasing storage time—a result that has indeed previously been reported for stored *Drosophila* sperm⁵.

The small lymphocytes in human peripheral blood are in a G_0 state and respond to PHA stimulation *in vitro* with the fast responding cells beginning DNA synthesis 24 h after stimulation and reaching mitosis at around 36 h (refs 6, 7). Following stimulation, cells may proceed through several mitotic cycles, with cycle times of around 16 h, over a period of a week or more in culture (unpublished data). Slow responding cells undergo a delayed transformation to a blast state such that they appear at their first mitosis many days after initial exposure to PHA. Fast responding cells are mainly T cells and slow responders contain a higher proportion of B cells⁸. To study the response of fast and slow developing cells to the induction of SCE and aberrations by mitomycin C, and to examine the effects of storage on induced damage, two types of experiment were performed.

For experiment 1, duplicate sets of blood cultures were set up in 10 ml RPMI 1640 medium (without serum and PHA) using 0.8 ml of heparinised whole blood from three healthy donors. One set was used as a control and the other treated with 6×10^{-7} M mitomycin C (Kyowa) for 1 h at 37 °C. The cells were then washed in medium and resuspended in fresh medium with serum, but without PHA, and incubated at 37 °C. Lymphocytes were stimulated to divide at 24 h intervals (from 0 to 9 days after treatment) by transferring to complete medium containing 20% fetal calf serum, 1% PHA (Wellcome), 1% glutamine, 100 units

penicillin, 100 µg streptomycin and 25 µM bromodeoxyuridine (BUdR). Stimulated cultures were kept in the dark at 37 °C and cells were collected at 72 h. Air-dried preparations were stained using the fluorescence plus Giemsa technique for differential chromatid staining⁹. With this protocol cells were kept for increasing periods, up to 9 days, in G₀ after mitomycin C treatment and samples of first and second division cells were available for up to 12 days after initial exposure to mitomycin C. Twenty second-division metaphases were analysed on each coded slide to determine SCE frequencies (Fig. 1). For chromosomal aberration incidence, first division metaphase cells which did not show differential staining were analysed from samples stimulated with PHA after 1, 5 and 8 days in culture and then fixed 72 h later (Table 1).

In the second experiment PHA and BUdR was added at the initiation of culture, the medium replaced with fresh complete medium every 72 h, and cells collected at daily intervals up to 7 days. The experiment was performed in two parts, and the SCE frequencies determined on coded slides are summarised in Fig. 2. The numbers of first division cells in late cultures were too small to give useful data on aberration frequencies.

The incidence of SCE in control cultures in experiment 1 showed no significant difference between donors or between culture times over a 9-day period. Mitomycin C exposure gave a typical eightfold increase in SCE levels over controls in cells stimulated over the period 1–4 days, but this was followed by a further significant increase (up to 100%) to a peak level at 6–8 days and a fall at 9 days. In cultures stimulated at time zero and sampled serially thereafter (experiment 2), there were no inter-donor differences and control samples showed a small increase in SCE with time in culture. Following mitomycin C treatment, there was again a rise in SCE frequency with time after exposure.

A trivial explanation of the increase in SCE with time after mitomycin C treatment would be that cells coming into their second mitosis around their sixth day in culture, whether stimulated at time zero and therefore 'slow' cells (experiment 2), or at day 4 and 'fast' cells (experiment 1), are more sensitive than other cells. This seems highly unlikely, since the samples scored

at these times represent different cell populations. To confirm this point, in a third experiment we exposed cells either to PHA plus mitomycin C at time zero and sampled at 3 and 4 days, or to PHA plus mitomycin C at day 4 and sampled on days 7 and 8. The mean frequencies of SCE, and of chromatid aberrations, at days 3 and 4 did not differ from those found at days 7 and 8 (Table 2), so that the latter cells were not more sensitive than the former. There is, however, evidence of differences in response between B and T lymphocytes to the induction of SCE by BUdR, with the former showing a lower response¹⁰. Since B cells may predominate in very late cultures, this may account for a decline in SCE frequency at this time, but we have no evidence of a differential sensitivity of B and T cells to damage by alkylating agents. We conclude, therefore, that the mitomycin C-induced increase in SCE with time after treatment is a time-dependent phenomenon that is not a consequence of differential sensitivity, but is a true storage effect.

The data on mitomycin C-induced aberration frequencies in first division cells, that is, non-harlequin-stained metaphases, are summarised in Table 1. Two significant findings are evident: first, there is a marked increase in aberrations with time after mitomycin C treatment, the incidence following PHA addition on day 8 being seven times greater than on day 1; second, this increase is contributed to almost equally by chromatid- and chromosome-type aberrations. It is well established that proliferating somatic cells exposed to alkylating agents contain only chromatid-type aberrations at their first post-treatment mitosis. These aberrations, in which the unit of exchange or breakage is the single chromatid, are produced following exposure of cells at any stage in the cell cycle, and are a consequence of a mis-replication at sites of damage during the replication phase^{11,12}. In contrast, X-ray exposure of unreplicated chromatids in the G₀ stage yields chromosome-type aberrations, where breakage and exchange occurs prior to replication and the aberrant structure is itself replicated at the S phase¹³. Lymphocyte nuclei exposed to mitomycin C are in a G₀ state at the time of treatment and in all short term cultures the only aberrations seen at mitotic first

† 40 second-division cells analysed at each point.

division in the first days following exposure are of the chromatid type. The presence of chromosome-type changes in first division cells when stored for periods of 5 to 8 days was therefore entirely unexpected.

Our demonstration of a large increase in chromosome aberrations and of a change in aberration type with increasing storage time following exposure to an alkylating agent, parallels earlier findings on *Drosophila* sperm. An aberration affecting a single chromatid in a fertilisation nucleus will segregate at mitosis to one of the daughter cells and may result in an individual mosaic for the abnormality, whereas a chromosome-type aberration, if viable, would be present in all descendent cells giving a whole-body mutant. Our result suggest that increased storage should result in a decreased proportion of mosaic mutants recovered and such a result has been reported for *Drosophila* sperm treated with triethylene melamine⁵.

We had previously shown that chromatid-type aberration frequencies in second division cells after exposure to alkylating agents are higher than in first division cells^{11,12}. This is consistent with the present findings and implies changes in the damaged DNA with time post-exposure. The interaction of mitomycin C with DNA is complex, although it is known that the semiquinone radical formed during its reduction in the cell binds very rapidly to DNA, particularly to the guanine moiety, and that the predominant site of alkylation is probably at the O^6 of

guanine¹⁴. Early changes in chromatid aberration frequencies may partly reflect single strand breakage due to chain instability following hydrolytic loss of alkylguanine, breakage arising either due to increased lability at the depurinated sites or to the action of an endonuclease II-type enzyme¹⁵. Mis-replication at sites of single strand damage may result in chromatid-type aberrations at replication, but chromosome-type aberrations require the presence of double-stranded scissions before replication¹⁶. Chain breakage following depurination may be a rare event, but chromosome-type aberrations may result from the coincidence of two single strand breaks that develop as secondary consequences of the alkylation that occurred many days earlier. Whatever the nature of the changes in lesions with time after exposure, these are more effective in increasing aberration frequency and result in only small increases in SCE.

Fig. 2 Incidence of SCE (60 second-division cells per point) in lymphocytes from three donors exposed to 6×10^{-7} M mitomycin C for 1 h and then immediately cultured in the presence of PHA and serum. Broken lines, control; solid lines, mitomycin C treated. ○, Experiment 2a; □, experiment 2b.

In most eukaryotic genomes, including human, 300-nucleotide repeated DNA sequences are interspersed with longer (~1,000 nucleotide) single copy sequences^{1–3}. We have recently found that most 300-nucleotide interspersed repeats in human share a common site for cleavage by the restriction enzyme *Alu* and should be regarded as a single family of sequences⁴. We designate this as the *Alu* family of sequences. Similarly, most of the 300-nucleotide inverted repeated sequences, which are also interspersed with single copy DNA, share this same restriction site and belong to the *Alu* family⁴. There are approximately 300,000 members of this family of sequences, which together make up at least 3% of the human genome⁴. It is conceivable that individual members of the *Alu* family repeats share only very limited regions of homology, one of which happens to contain the restriction site for *Alu* and others which share the additional restriction sites reported here. In this case, members of the *Alu* family could be essentially different DNA sequences. DNA renaturation studies support the alternative view that members of the *Alu* family share extensive homology over the entire sequence length⁴. According to this view, individual members of the family could exhibit some divergence from the

As one control, we compare the fidelity of the sequence and its complement (Fig. 2). Complementary sequences were obtained as shown in Fig. 1a. In one portion of the proposed average sequence (positions -92 to -30) there are 11 differences in 62 assignments, which corresponds to an 18% sequence mismatching. In the other portion of the sequence (positions +12 to +69) there is 5% mismatching (3 differences in 56 assignments) between the sequence and its complement (Fig. 2). These values compare favourably to estimates from thermal stability studies which indicate an average of 12% mismatching in renatured interspersed repeated human DNA sequences¹.

As a second control on the accuracy of this sequence we have also determined the base sequence of some cloned members of the *Alu* family. Clones were constructed by ligating synthetic *Bam*HI linkers on the 300-nucleotide repeated sequences described above using a modification of a procedure used to clone sea urchin repeats⁷. These were propagated by insertion into the *Bam*HI site of the episome pBR322 and grown under P3, EK1 containment.

One clone, clone 8, was base sequenced in its entirety; another, clone 2, has been partially sequenced. The sequencing techniques used for this determination are summarised in Fig. 2, and we regard the assignments as being unambiguous. The sequences of these two clones are closely related to each other and to the average base sequence described above (Fig. 2). With the exception of a deletion in clone 8 at position 33, the overall sequence mismatching between clones 2 and 8 is 24% (27 differences in 113 shared sites). Twelve of these mismatches are clustered near position +75. A more extensive comparison of additional cloned sequences is required to establish whether

mutations are randomly distributed or clustered at certain preferred sites. It is especially interesting to compare the relative sequence fidelity of the two clones and the *Alu* family in the region shared by all three sequences, positions +3 to +69. There is 18% mismatching (11 differences in 61 sites) between clones 2 and 8 in this region. There is 22% mismatching (14.5 differences in 67 sites) between the *Alu* family and clone 8 and 21% mismatching (13 differences in 62 sites) between the *Alu* family and clone 2 in this shared region. The agreement between these estimates suggests that the average sequence proposed for the *Alu* family resembles the actual sequence as closely as any individual cloned member of the family. As previously noted, we expect 12% mismatching of renatured interspersed repeated human DNA⁵. Our representation of the *Alu* family therefore approximates the fidelity with which the sequence has been evolutionarily conserved.

Jelinek and co-workers have found that the repetitive double strand regions in HeLa cell heterogeneous nuclear RNA (hnRNA) have a very simple fingerprint⁸⁻¹⁰ dominated by six prominent oligonucleotides. This implies that repetitive hnRNA may contain one or at most a few distinct families of sequences⁸⁻¹⁰. In support of this conclusion, we find that five of the six oligonucleotides (oligonucleotides 1, 2, 3, 5, 6 reported by Jelinek *et al.*⁸) are present or approximately represented in the *Alu* family of sequences (Fig. 2). The remaining oligonucleotide 4 was later found to be a mixture of sequences and was not further characterised⁹. We find two sites in the *Alu* family which resemble oligonucleotide 4 and may be the composite source of that sequence (Fig. 2). The *Alu* family of repeated DNA sequences is sufficient to account for part if not all of the repetitive hnRNA sequences described by Jelinek and his colleagues⁸⁻¹⁰. As further evidence for this conclusion, Jelinek observed the same six prominent oligonucleotides in fingerprints of *in vitro* transcripts of inverted repeated DNA sequences⁹. As noted above, the 300-nucleotide inverted repeated sequences are members of the *Alu* family and should, as Jelinek observed, also contain these oligonucleotides.

We have restricted our description of this family of sequences to the human genome. However, work in progress in our laboratory indicates that a closely related family of sequences is found in all primate genomes (galago, monkey and human). Furthermore, Jelinek's observation of a single prominent oligonucleotide in the repetitive double-strand regions of hamster hnRNA is sufficient evidence to suggest that, in analogy to human, the hamster genome is also dominated by a single family of interspersed repetitive DNA sequences¹¹.

The biological function of this family of sequences is unknown. We and our colleagues have recently noted sequence similarities between a selected portion of the *Alu* family and several other RNA or DNA sequences, which are known or suspected to be involved in DNA replication, transcription control, and mRNA processing¹². Together these observations reinforce our belief that a family of DNA sequences which includes 300,000 highly conserved members interspersed throughout much of the mammalian genome, must have an important function.

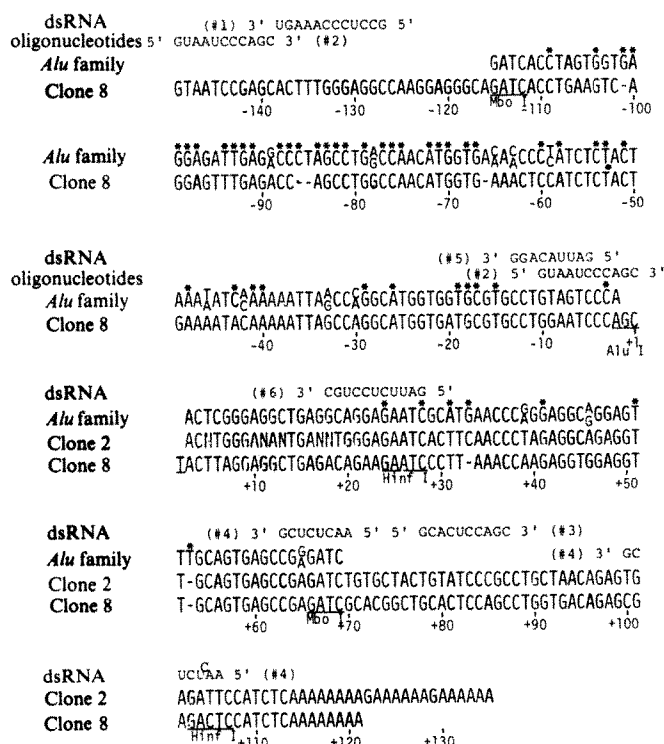

Fig. 2 The sequences of the *Alu* family and clones 2 and 8 are shown in large type. Since the ends of the sequence are not precisely defined, the sequence is numbered in both directions from the *Alu*I site. The method for determining the average sequence of the *Alu* family is described in the text and Fig. 1a. Asterisks designate sites at which the readings of either the sequence or its complement were ambiguous (see Fig. 1b). Positions at which the sequence and its complement did not agree are indicated by the presence of two bases. In the base pair fidelity calculations presented in the text these positions are assigned a value of 0.5 (that is, half mismatched). Clone 2 was cleaved at the artificial *Bam*HI linkers (see text), fill-in labelled at the 3' ends using α -³²P and reverse transcriptase and strand separated on a polyacrylamide gel. It was then sequenced by the Maxam-Gilbert technique⁶. Clone 2 was cleaved at the synthetic *Bam*HI sites, labelled at the 5' end with γ -³²P and polynucleotide kinase and cleaved with *Alu*I. The sequence between the right *Bam*HI site and the *Alu*I site was determined by the Maxam-Gilbert method. All the DNA sequences read from 5' to 3'. A deletion in one of the sequences compared to another is indicated as (-). The dsRNA oligonucleotides are shown in smaller type. The sequences of these oligonucleotides (1 to 6) are from the results of Jelinek and coworkers⁸⁻¹⁰. The polarity of the RNA strands is indicated in the figure.

MATTERS ARISING

Bragg intensities near structural phase transitions

IN a letter to *Nature* Åsbrink and Hong reported an increase of X-ray reflection intensity and profile widths at the low-to-high- V_3O_5 phase transition state¹. The oldest reference I know of to the increase of X-ray intensity near structural phase transitions is that of De Quervain² in 1944. The effect was observed in a ferroelectric material (KDP) of which large rather perfect crystals can easily be grown. As these crystals show severe extinction, any disturbance caused by a phase transition is liable to increase the reflectivity. Since then, this effect has been observed rather often near first-order phase transitions, and also with neutron or γ -ray scattering³. It has been used as a very accurate indication for the occurrence of the transition^{4,5} in a pressure cell. (We commonly use a series of crystals with various transition temperatures for accurate cryostat calibration.)

As this overshooting concerns integrated intensities, the width of the reflection profiles also increases. Various authors have used the information which lies in the variation near the transition of the profile shapes to characterise the state of the crystal near T_c . For example, Zeyen *et al.*^{6,7} have studied the reflection profiles of DKDP crystals during its ferroelectric first-order phase transition using high precision cryogenics⁸ and high resolution neutron diffraction techniques⁹. They investigated the spatial distribution of the phase mixing at T_c where both the paraelectric and the ferroelectric phases coexist in the crystal in a particular arrangement which actually minimises elastic and electrostatic (polarised domains) energies and depends on the structural change at T_c . Following their model the DKDP crystal forms a multi-layer of alternating paraelectric and ferroelectric sheets. It explains directly the overshooting intensity near T_c . The existence of these layers has in the meantime been confirmed directly by optical observation in a special cryostat¹⁰. Other systems giving different spatial arrangements have also been studied.

ÅSBRINK AND HONG REPLY—We thank Zeyen for information on early discussions about intensity overshoot in connection with studies on KH_2PO_4 and KD_2PO_4 .

The possibility of phase mixing during the transition occurred to us; however, we had to discard it as several reflections did not even exhibit the profile widening at $t_T = 154.7^\circ\text{C}$ required by the difference in unit cell dimensions between the two V_3O_5 phases. (We made the comparative profile width measurements at 153 and 156°C for low- and high- V_3O_5 , respectively, and assumed that the entire change of unit cell dimensions between those temperatures took place at t_T .)

Magnetostратigraphy, biostratigraphy and geochronology of Cretaceous-Tertiary boundary sediments, Red Deer Valley

LERBEKMO *ET AL.*¹ have presented some valuable radiometric data from an important continental sedimentary sequence which includes the Cretaceous-Tertiary boundary in Alberta. However, the palaeomagnetic data which they presented in their Fig. 2 show considerable scatter and do not provide a well defined polarity zonation.

Lerbekmo *et al.* correlate their magnetic polarity zonation from the Red Deer Valley with the magnetic polarity time scale. They note that the Cretaceous-Tertiary boundary, as recognised by marine biozonations, occurs near the base of anomaly 29. Lerbekmo *et al.* then concluded that the long normal polarity zone overlying the Cretaceous-Tertiary boundary in the Red Deer Valley, as recognised by dinosaur extinction and palynofloral zones, must correlate with anomaly 29. We consider this correlation to be circular reasoning based on the incorrect presumption that the Cretaceous-Tertiary boundary in the Red Deer Valley is synchronous with the Cretaceous-Tertiary boundary as determined by marine biozonations. This normal polarity zone in the Red Deer Valley could correlate with anomaly 28 or even anomaly 27. The magnetic polarity zonation in the Red Deer Valley does not show a convincing correlation to the magnetic polarity time scale. Thus, the conclusions reached by Lerbekmo *et al.*

based on their correlation are rather speculative.

In addition, Lerbekmo *et al.* proposed an alternative to our^{2,3} correlation between the San Juan Basin magnetic polarity zonation and the magnetic polarity time scale. They suggested that the normal polarity zone which we correlated with anomaly 29 should be correlated with a normal polarity interval between anomalies 29 and 30. However, there is no evidence for such a normal polarity interval in either of the two magnetostratigraphic sections at Gubbio, Italy^{4,5} nor in the magnetostratigraphic section at Moria, Italy⁶ nor in the marine magnetic anomaly record⁷. The palaeomagnetic data from the San Juan Basin provide a well defined magnetic polarity zonation which shows a strong correlation with the magnetic polarity time scale^{2,3}. We do not agree with Lerbekmo *et al.*'s reinterpretation of our data.

Lastly, we do not agree that there are "palaeontological discrepancies between the New Mexico, Alberta, and Gubbio, Italy sections with respect to the Cretaceous-Tertiary boundary". As we pointed out², the Cretaceous-Tertiary boundary is defined by extinction of marine invertebrates but is recognised in terrestrial sedimentary sequences by the last occurrence of dinosaur fossils. These two biological events need not have occurred synchronously and marine/non-marine intertonguing relationships do not provide enough precision to test for global synchronicity of this geological-time boundary. However, magnetostratigraphy does provide a possible technique for determining the temporal relationship of dinosaur extinction and marine invertebrate extinctions marking the Cretaceous-Tertiary boundary. Thus our magnetostratigraphic data which indicate a lack of synchronicity between dinosaur extinction in the San Juan Basin and the Cretaceous-Tertiary boundary at Gubbio, Italy do not constitute a palaeontological discrepancy as implied by Lerbekmo *et al.*

LERBEKMO *ET AL.* REPLY—Butler and Lindsay have focused attention on some of the problems in magnetostratigraphic correlation. They point out that our palaeomagnetic data show considerable scatter and do not provide a well defined polarity zonation. This reiterates the statement in our original article. Nevertheless, there is a stratigraphic zonation present—the data are not randomly scattered. We believe the key to interpretation of this type of data is the recognition of the importance of viscous and/or chemical overprinting; nature has not provided ideal material and we have attempted a rational interpretation following the reasoning of Hillhouse *et al.*¹. A closely comparable study involving the same problems, and following essentially the same scheme has been reported by Brown *et al.*². We are convinced that a real pattern of normal and reversed polarity emerges from our data, although some overprinting may still be present.

Butler and Lindsay suggest that we have used circular reasoning in our anomaly matching, which we have not. This can probably be attributed to the limited palaeontological background information contained in our original article. In fact, we believe that our correlation of the Red Deer Valley section with the Gubbio section in Italy is unambiguous for the following reasons.

The palynomorphic change which takes place just above the Nevis coal seam in Alberta³ and at the Hell Creek (Lance)—Fort Union contact in Montana and Wyoming³, also takes place at the Hell Creek—Ludlow (Lignite Beds) contact in North Dakota in the type area of the Cannonball Formation⁴. The Ludlow there is 5–20 m thick and is overlain by the marine Cannonball which reaches a thickness of 125 m in the subsurface at Garrison Dam⁵. Foraminifera recovered from the Garrison Dam core place the entire formation in the *Globigerina edita* zone, which is the lowest Palaeocene foraminiferal zone and is equated⁵ to the *Globorotalia pseudobulloides* zone plus the thin *Globigerina eugubina* zone (which occur in the Gubbio section). The Cannonball Formation spans the *Globorotalia pseudobulloides* zone and is separated from the Cretaceous–Tertiary boundary below, as defined by palynomorphs, by about 20 m of Lignite Beds (=Ludlow)^{4,5}. The *Globorotalia pseudobulloides* zone at Gubbio encompasses part of anomaly 28, all of anomaly 29 and part of the reversed zone between anomalies 29 and 30 (ref. 6). Therefore, if the palynomorphic change equated with the Cretaceous–Tertiary boundary in Alberta, Montana, North Dakota and Wyoming³ is essentially synchronous throughout this area, as believed⁴, this palynomorphic boundary and the highest occurrences of dinosaurs are in the same reversed zone in which the foraminiferal Cretaceous–Tertiary boundary takes

place in Italy (that is between anomalies 29 and 30).

The anomaly matching by Butler *et al.*⁷ and Lindsay *et al.*⁸ is not infallible; whether or not the results summarised in Fig. 2 of ref. 8 constitute a “strong correlation with the magnetic polarity time scale” is debatable. The problem of ‘extra’ polarity intervals arises. In their comment above Butler and Lindsay question the validity of an additional normal interval between 29 and 30. However, in Fig. 2 of ref. 8 two ‘extra’ polarity intervals are shown which do not appear in the seafloor polarity record⁹. We expect that detailed palaeomagnetic studies of this type will reveal short magnetic zones not now recognised in the seafloor anomaly pattern, but much further work will be required to separate these from fictitious overprinted intervals.

British Tertiary Igneous Province probably not associated with East Greenland lavas

IN their recent article Carter *et al.*¹ discuss the source regions of continental basalts extruded round the North Atlantic in the early Tertiary. They made the common assumption that the British Tertiary Igneous Province (BTIP) was formed as a result of the rifting which led to the separation of Greenland from Europe. Their reason for this assumption was presumably that the formation of the BTIP was close in space and time to the

rifting. However, this similarity may be more apparent than real and be misleading by concealing significant differences, summarised below.

Carter *et al.* give the duration of activity in the BTIP as 66–50 Myr ago. Although such a spread of dates—and greater—can be found in the literature, note that the province has proved particularly difficult to date accurately, and many published dates are inconsistent with the stratigraphy, for example K–Ar dates for Faeroes² and Mull dykes³. If only the most reliable dates are used, which means chiefly ⁴⁰Ar/³⁹Ar plateau and Rb/Sr isochron ages, most activity is found to have occurred about 60 Myr ago (Table 1). (All dates quoted here have been adjusted to the decay constants and so on of Steiger and Jäger⁴.) Only Lundy is clearly younger.

The time of opening of the North-east Atlantic is not yet agreed, but is usually assumed to have just preceded the formation of magnetic anomaly 24. The age of this anomaly is deduced by calibrating the anomaly pattern of Heirtzler *et al.*⁵ at various points; because the spreading rate was probably not uniform this leads to a range of estimates for the age of anomaly 24. However, polarity time scales which have been calibrated in the Palaeocene^{6–8} assign it ages of 50.3, 53.4 and 54.4 Myr, respectively. Although the Greenland basalts must be somewhat older than this, it seems unlikely that they are contemporaneous with the BTIP, with the possible exception of Lundy.

Another difference is that activity on the British side of the North-east Atlantic—to be occurred in discrete areas. Most of these areas lie roughly on a line joining the Faeroes to Lundy (St Kilda and Rockall lie well to the west) which diverges at an angle of ~55° from the margin of the Atlantic, according to the reconstruction of Bullard *et al.*⁹. Thus Arran, for example, is a perpendicular distance of ~300 km from the margin, while Lundy (the part of the BTIP most likely to be contemporaneous with the rifting) is over 500 km distant. In contrast, the Greenland activity lies within 150 km of the margin.

The East Greenland coast has a flexure and associated dyke swarm. In contrast, the BTIP has no flexure and the regional dyke swarms of the separate areas, although roughly parallel to each other, are *en echelon*; these swarms are not what

Table 1 ⁴⁰Ar/³⁹Ar plateau and Rb/Sr isochron dating

Area and rock	Method	Age (Myr)	Ref.
Arran: Northern Granite	⁴⁰ Ar/ ³⁹ Ar plateau	60.4 ± 0.6	10
Mournes: granite	⁴⁰ Ar/ ³⁹ Ar plateau	59.7 ± 1.6	10
Mull: dyke cutting Loch Bà Felsite	⁴⁰ Ar/ ³⁹ Ar plateau	60.3 ± 3	10
Mull: centre 3 granite	Rb/Sr isochron	58.2 ± 2.5	11
Antrim: basalts	K/Ar isochron	~60	12
Lundy: granite	Rb/Sr isochron	53 ± 2, 55 ± 3	13
Lundy: granite	⁴⁰ Ar/ ³⁹ Ar plateau	53.4 ± 1.4	14

would be expected along, or beside, a simple tensional split but rather, say, what would result from a southward movement of Ireland relative to Great Britain.

Most of the activity of the BTIP probably preceded the opening of the North-east Atlantic and the Greenland activity by several million years; it does not occur along the margins of the rift, and occurred in a stress field that does not seem to be related to that of an opening ocean.

These observations do not affect the conclusion of Carter *et al.*, that there is no evidence for an undepleted mantle source-region for any of the basalts they discussed. However, their assumption that the BTIP is simply due to the formation of the North-east Atlantic oversimplifies our understanding of how the BTIP formed. Here it is relevant that they point out that the BTIP may be anomalous as there may have been "overall higher temperatures in the lower crust in North-west Scotland at the time of basalt eruption than elsewhere in the North Atlantic Tertiary Province".

Perhaps it just was not part of this province!

Cubomedusae belong to the class Cubozoa, not Scyphozoa

IN their report on the neurophysiology of *Carybdea rastonii* Haacke (a cubomedusa), Satterlie and Spencer¹ emphasised that "... properties of the neuromuscular system ... clearly show it to be of the scyphozoan type ...". They also name the Cubomedusae as an order within the class Scyphozoa according to Haeckel's taxonomic scheme². Since the discovery of the first polyp of a cubomedusa³, Werner^{4–7} and Chapman^{7,8} have made extensive studies of the anatomy, behaviour, life history and systematic position of members of this group. The results of these studies led Werner to give

the Cubomedusae the rank of a class (Cubozoa)^{4,5}. This conclusion was supported by Chapman's study of the microanatomy of a cubopolyp⁸.

The principal factor which has led to the new classification is the structure of the polyp. Those cubopolyps which have been studied (*Tripedalia* and *Carybdea*) differ from polyps of the class Scyphozoa in that they lack, among other features, the gastric septa and tetramerous symmetry which are diagnostic of scyphopolyps^{5,6,8–10}. The cubopolyps share radial symmetry, lateral budding, capitate tentacles and other important features with hydrozoan polyps and also possess unique features^{5,6,8}. The neuromuscular system (which Satterlie and Spencer¹ equate with that of the Scyphozoa), like the features mentioned above, clearly illustrates the mixture of unique, scyphozoan-, and hydrozoan-like features in the Cubozoa. For example, it has long been known that cubomedusae possess a marginal nerve ring^{2,9}, like the hydromedusae but unlike the scyphomedusae. A unique feature of the Cubozoa is the presence of an ectodermal-endodermal nerve-ring pair in the polyp⁸. Although Satterlie and Spencer¹ cite the paper by Werner *et al.*⁶ on the neuromuscular system of a cubopolyp, they discuss in their own article only the medusa of *Carybdea* and only scyphozoan-like features of the medusa.

When one is dealing with organisms with a complex life history, such as coelenterates, one must bear in mind all stages of the life cycle if one wishes to draw conclusions about taxonomic position. Satterlie and Spencer's¹ fascinating findings on the neurophysiology of *Carybdea* do not support the retention of the Cubomedusae in the class Scyphozoa but do provide further support for Werner's^{4,5} theory that the Cubozoa are intermediate between the Scyphozoa and Hydrozoa and that the Scyphozoa are the class most similar to the ancestors of the three groups.

SATTERLIE AND SPENCER REPLY—
Our article was not intended to give

definitive evidence for the taxonomic position of the Cubomedusae. However, judged by the neuromuscular properties of the swimming system of *Carybdea*, the medusae strongly resemble the scyphomedusae. This similarity is so convincing as to make it unnecessary to create a new class, the Cubozoa, to accommodate any unique features. In addition, the structure and function of the swimming system of *Carybdea* is unlike any known hydromedusan system.

The one cubomedusan feature frequently considered hydrozoan-like, the subumbrellar nerve ring, is not structurally or functionally similar to the marginal nerve rings of hydromedusae. In the latter, swimming pacemakers are distributed throughout the inner nerve ring, as an electrically coupled network of 'giant' neurones. In both cubomedusae and scyphomedusae, the swimming pacemakers are restricted to the rhopalial. Transmission of pacemaker output throughout the subumbrellar muscle sheet in both cubomedusae and scyphomedusae is through networks of large bi- and tri-polar neurones, making up subumbrellar nerve nets. Although subumbrellar nerve nets are present in some hydromedusae, the subumbrellar muscle cells show widespread intercellular electrical coupling, and in some cases, make up a conducting musculo-epithelium. Ultrastructural evidence argues against such electrical coupling in cubomedusae. Each swimming contraction of hydromedusae is an all-or-none event, accompanied by an all-or-none action potential in the muscle sheet. In comparison, both cubomedusae and scyphomedusae exhibit graded muscle contractions, and at least in *Carybdea*, graded muscle potentials. As this short comparison points out, not only is there a lack of similarity between the hydromedusan and cubomedusan swimming systems but also a lack of originality on the part of the cubomedusae, as all features are distinctly scyphozoan-like.

As Leonard points out, most of the evidence for proposing a new class comes from work on the structure of cubopolyps. It is difficult to determine whether some of the structural characteristics of cubopolyps, such as the lack of tetramerous symmetry and gastric septa, are primitive features or secondarily derived from a true scyphozoan ancestor. Cubomedusae exhibit structural specialisations in both stages of their life cycle; however, at least in the medusa generation, these specialisations are morphologically and physiologically consistent with the scyphozoan line.

Enhanced excision of O^6 -alkylguanine in rat liver by pretreatment with acetylaminofluorene

AS recently reported by Buckley *et al.*¹, a diet containing 0.06% 2-acetylaminofluorene (AAF) established in rats a condition in which the liver of the animals had an increased capacity for removing O^6 -methylguanine from DNA produced by a single dose of dimethylnitrosamine (DMN). These observations are open to many interesting interpretations. However, the authors concentrated exclusively on the concept of induction of specific repair enzymes by the presence of damage from AAF adducts. This interpretation does not pay due attention to the biological state of the cell population in the liver at the time of the investigation.

Chronic ingestion of a liver carcinogen such as AAF will stimulate the liver into hyperplasia. Although the authors specifically excluded animals that had nodular livers, it is likely that livers of all animals at the end of this chronic treatment will contain an increased proliferative population^{2,3}. Passage between the non-cycling and proliferative phases of a cell population alters the activity of many enzymes involved in DNA replication and repair. Peripheral lymphocytes stimulated to proliferate by phytohaemagglutinin increase their capacity for repair⁴ and synthesise a specific repair enzyme, uracil glycosylase⁵. In the rat liver, DNA polymerase β , which may participate in excision repair, increases during regenerative hyperplasia following partial hepatectomy⁶. The repair systems do not all respond equally, because the system that removes O^6 -methylguanine increases during liver hyperplasia after chronic treatment with DMN, whereas that for removing N^3 -methyladenine or N^7 -methylguanine does not⁷. Excision repair seems to be particularly responsive to the proliferative state of a cell population⁸⁻¹⁰. One interpretation of the observations of Buckley *et al.*¹ may therefore simply be that they represent the differences between the repair capacity of a quiescent relative to a proliferating cell population. The increased repair of O^6 -methylguanine would not relate specifically to signals from damaged sites inducing the synthesis of new enzymes, but rather to a more generalised consequence of stimulation of proliferation.

Buckley *et al.* imply that exposure to AAF induces the repair of lesions formed by an unrelated carcinogen, DMN. The lesions formed by AAF and the O^6 -methylguanine produced by DMN are not, however, as different as might be expected if one considers the pathways by which they are repaired. Both kinds of lesion can be repaired by the nucleotide excision repair pathway¹¹. This system removes pyrimidine dimers produced by UV light and is regulated by the genes

associated with the human disease xeroderma pigmentosum (XP)¹². The autosomal recessive mutations in XP eliminate the capacity to remove O^6 -methylguanine, O^6 -ethylguanine, pyrimidine dimers, and the lesions produced by *N*-acetoxy-AAF¹³⁻¹⁶. Interestingly, O^6 -methylguanine is not repaired by the nucleotide excision repair system in *Escherichia coli*, although it is in mammalian cells^{15,16}, suggesting that prokaryotic systems may be very poor models to use in the interpretation of observations of O^6 -methylguanine in mammalian cells.

Buckley *et al.* cite evidence for the induction of post-replication repair by *N*-acetoxy-AAF-treated Chinese hamster cells¹⁷, but that observation only demonstrated alterations in semi-conservative DNA replication confined to the first few hours after an acute dose. Those alterations involved the growth of nascent DNA chains, and did not involve any change in the repair of lesions on the parental DNA; also, they have been interpreted elsewhere in a manner that does not invoke the induction of any system¹⁸.

Therefore, we suggest that a change in the excision capacity of liver by pretreatment with AAF more probably reflects the production of a spectrum of enzymes associated with cell proliferation, especially for DNA replication and repair, than the specific induction of unique repair enzymes. Moreover, we should also point out an interesting implication of observations of Buckley *et al.* in relation to the role of O^6 -methylguanine as a critical lesion for carcinogenesis by alkylating agents¹⁹. When rats were given the same feeding regimen of AAF and DMN, the subsequent yield of hepatocellular carcinomas reached nearly 100%, whereas a single dose of DMN given alone produced no liver cancers²⁰. Thus, increased repair of O^6 -methylguanine correlates with increased susceptibility to hepatocarcinogenesis, whereas the opposite correlation prevails in the neonatal rat brain, in which decreased repair of O^6 -methylguanine correlates with elevated carcinogenesis²¹. These contrasting correlations indicate that any attempt to ascribe a unique, definite role to O^6 -alkylguanine in carcinogenesis is premature; the role of this product and its repair are not yet fully understood. At the very least, the balance between DNA repair and DNA replication in each experimental situation needs to be carefully considered.

BUCKLEY, O'CONNOR AND CRAIG
REPLY—Although more detailed information will be available when a fuller report is published on the basis of our recent study¹, two comments should be made on the matters raised by Cleaver and Kaufmann. First, we did not intend to imply that our interpretation rested exclusively on the induction of specific repair enzyme systems. Had that been the case we would not have used the phrase "general repair mechanism". Second, with regard to the final statement on the role of O^6 -alkylation of guanine in DNA, we agree that an increased capacity for the repair of O^6 -methylguanine in liver DNA correlates with a high susceptibility to hepatocarcinogenesis in the case of rats chronically exposed to dimethylnitrosamine. Indeed, this may also be the case in our experiments with rats exposed to AAF, although the situation has not been evaluated in our own Wistar rats. While recognising that the role of O^6 -alkylguanine in carcinogenesis is not fully understood it seems unreasonable to consider just two experimental situations (increased O^6 -methylguanine repair after pretreatment and the persistence of O^6 -alkylguanine in the brain of neonatal rats with respect to tumour formation) and not to take into account the considerable information now available (reviewed in refs 2-5). In fact, from reports referred to in these reviews it is clear that careful consideration has been given to the relevance of DNA repair and DNA replication.

BOOK REVIEWS

Meeting the challenge of eukaryotes

Kenneth Burton

LIKE the well-known first volume that appeared over five years ago (reviewed in *Nature* 252, 145; 1974), this book is a selection of topics written by different authors for the advanced student and aimed at the niche between basic textbooks and specialist reviews. The earlier volume was rather hefty and had mainly general or prokaryotic topics; the new one is of a more reasonable size and its fifteen chapters illustrate the growing confidence of molecular biologists to approach the many challenges posed by eukaryotes.

The authors have generally avoided the temptation to be too comprehensive and sometimes linger to analyse controversies, unanswered problems or the limitations of experimental techniques. I doubt if there can be any biochemist already so knowledgeable over the whole field that he could not find a good number of novel and intriguing topics in the book. Yet no chapter should be beyond the reach of a final-year honours undergraduate, apart from the theory in Blake's article on X-ray crystallography which needs particularly good mathematical preparation. Without it, however, much can still be gleaned including an illuminating discussion of structures derived from single crystal X-ray diffraction. The full appreciation of Tipton's account of the kinetic properties of allosteric and co-operative enzymes also needs a mathematical grasp that is regrettably beyond that of some undergraduate biochemists.

Several other chapters are also of general application to many areas of biochemistry. Nigel Brown knew he had a difficult task to review nucleic acid sequencing, for here the speed of biochemical innovation outpaces the leisurely tread of book publishing. His article was splendid when it was written in

Companion to Biochemistry. Vol. 2. Edited by A.T. Bull, J.R. Lagnado, J.O. Thomas and K.F. Tipton. Pp. 490. (Longman: Harlow, UK, 1979.) £13.95.

1977 but the dideoxynucleotide chain termination method for DNA sequencing and rapid methods for RNA sequencing were not originally included and only get a very brief mention in an addendum. Where space must represent cost, it is surprising to see nearly a page given to the formulae of carbodiimide modification of uracil as well as six pages to the complete sequence of ϕ X174 DNA, however splendid and important the elucidation of that sequence may have been. Glover and Rigby give a lively and stimulating account of gene cloning and recombinant DNA procedures, and how they can be used. As any *Nature* reader will know, this field is also moving forward at a rush aided by the fast methods of DNA sequencing. Again, important applications and developments since the middle of 1977 are not discussed fully though some are mentioned in the inevitable addendum, with only four citations from 1978 and, of course, none from 1979. Thomas clearly expounds the more incisive arguments about the basic molecular structure of chromatin.

Hardy's chapter on ribosomes succeeds in being most useful for the non-specialist but there are other more detailed (and often turgid) reviews on ribosomes elsewhere. Campbell contributes a lucid, well-argued article that is a joy to read on the biosynthesis of proteins destined for secretion. Rumsby's chapter on membranes is less successful: the prose style is guaranteed to switch off all but the most ardent student (for example, "A

consideration of the phase properties of complex lipids is fundamental in understanding current views on the structure of lipids in biological membranes. On heating complex lipids exhibit an intermediate mesomorphic ..."). Moreover, there are unfortunate mistakes in the calculation of protein/lipid ratios in Table 6.3.

Hales, Elder and Davies have chosen to comment on general aspects of clinical biochemistry and the training of clinical biochemists as well as to discuss inherited abnormalities of enzyme function and the use of immunological assays, especially in endocrinology. These discussions are excellent, apart from the lack of up to date references for the last topic.

The remaining chapters are in more specialised fields, such as cell-surface receptors and neurotransmitters (Michell), macromolecular aspects of nervous communication (Lagnado and Beale), complement (Reid), photosynthesis (Gregory) and vision (Voaden). Several of these authors offer aperitifs of relevant background biology that whet the appetite for their main course. Laskey writes most lucidly on the biochemical basis of cell specialisations in early embryonic development. He emphasises DNA

replication, transcription and protein synthesis with an analytical approach that is free from unprofitable speculation. Intermediary metabolism of animals is not given a chapter and plants get only one, on photosynthesis.

I am sure that this book will be read, studied and enjoyed with much profit by advanced students and teachers of biochemistry, even though some chapters are already somewhat obsolete, so raising the question whether quicker ways of production cannot be found for this type of

material. Although there is no use of colour, the presentation is generally good; the type is clear, and there are many good line diagrams and a full subject index. Photographic material is well-chosen, though the quality of reproduction might have been better. The cost per page is not unreasonable by comparison with other publications of similar purpose, such as *Essays in Biochemistry*. □

Kenneth Burton is Professor of Biochemistry at the University of Newcastle upon Tyne, UK.

Ocean sound speed fluctuations

John A. DeSanto

Sound Transmission through a Fluctuating Ocean. Edited by S. M. Flatte. Pp. 299. (Cambridge University Press: Cambridge, 1979.) £17.50.

THE book is a very well-edited collection of results arising out of the Jason group of the Advanced Research Projects Agency. It presents their theoretical treatment of the effects of a particular model of ocean sound speed fluctuations (due solely to internal waves) on acoustic propagation, and compares the results with those of three experiments, one in the Western Atlantic (Eluthera-Bermuda), one in the Eastern Atlantic (Azores), and one in the North-eastern Pacific (Cobb Seamount).

Both deterministic and statistical properties of the ocean differ from those of other media. Deterministically, the ocean is refractive in depth (unlike atmospheric optics). Statistically, ocean fluctuations differ from those of homogeneous isotropic turbulence, for example, by being anisotropic, inhomogeneous and by having a different spectral function.

The effects on an acoustic signal propagating through the random ocean region depend on the size (diffractive effect) and strength (simply, the rms phase variation) of the random sound speed inhomogeneities. If the region is a weak scatterer ('unsaturated') neither signal amplitude nor phase fluctuate rapidly. For a stronger scatterer ('partially saturated') the phase begins to fluctuate rapidly, and for a very strong scatterer ('saturated') both phase and amplitude fluctuate rapidly. Also, the longer the propagation range and/or the higher the frequency the more the saturation.

The book contains several parts. Part I is on the ocean environment (ocean structure, planetary waves and eddies, and linear internal waves), and is an excellent introduction to the physics of the ocean

and the internal wave fluctuation model used throughout. The fluctuations are thus modelled as arising solely from that spectral window of ocean variability bounded below by the Coriolis (inertial) frequency and above by the Väisälä (buoyancy) frequency.

In Parts II, III and IV, the theoretical methods of sound transmission are developed and interrelated. Path-integral methods (useful in the saturated region), the Rytov approximation (unsaturated region), and the parabolic approximation are all developed, with particular attention paid to ray-theory methods. Of particular use is the discussion of the statistics of acoustic signals in regimes of different saturation.

Do internal waves account for acoustic fluctuations? Part V compares the theoretical predictions to the three experiments. With this extensive and careful development one rather tends to expect a smashing success. It isn't so. The results are mixed. For the (saturated)

Eluthera-Bermuda experiment the rms phase rate and Cartesian signal statistics are predicted well, phase and intensity spectra poorly. For the Cobb Seamount experiment (unsaturated) the internal wave model doesn't account for the measured intensity fluctuations. For the Azores experiment (partial saturation) the agreement is generally good.

My opinion is that the mixed results should not detract from this well written book. It contains a great deal of information, a consistent focused methodology, and the starting point for much additional work. It is suited to an advanced graduate course; and its balance of theory, computations and experimental comparison can serve as a model for extension to the effects of other ocean spectral regimes on acoustic propagation. □

John A. DeSanto is a research physicist at the Naval Research Laboratory, Washington, DC.

Geothermal energy

E. R. Oxburgh

Geothermal Energy. By H. Christopher H. Armstead. Pp. 357. (E. and F. N. Spon: London, 1978.) £10.50.

OF THE 'alternative energy' resources attracting attention in the early seventies at the time of the rapid rise in world oil prices, geothermal energy is probably the only one for which the expectations are better today than they were five years ago. On the other hand, it must be admitted that at that time expectations were rather low, certainly in Britain.

The exploitation of geothermal energy involves extracting water from sufficiently deep in the ground that it arrives at the surface hot enough for useful heat to be

obtained from it. In geothermal prospecting the aim is to identify places where subsurface temperatures are abnormally high and where, at the same time, the rocks are sufficiently permeable to permit the circulation of water through them. Although in principle any desired temperature up to about 250°C could be reached by deep drilling, in many places this value would be reached only at depths of 10-12 kilometres, close to the depth limits of present drilling technology. Drilling costs are so high, however, that at present the economic viability of a geothermal prospect depends on whether water at useful temperatures can be obtained from depths of less than about 4 kilometres. Of the geothermal power in use today (providing about 0.25% of the world's electrical energy) the greater part is derived from much shallower depths than this; in volcanic areas it is often possible to work with holes of the order of a kilometre deep.

Princeton: Monographs in Population Biology

Robert M. May, Editor

"The Princeton series 'Monographs in Population Biology' has provided a forum for leading ecological and evolutionary biologists for over a decade."—*Animal Behaviour*

"Since *The Theory of Island Biogeography* by R.H. MacArthur and E.O. Wilson launched this series in 1967, each successive volume has helped to transform ecology into more of a statistical subject."—*New Scientist*

Caste and Ecology in the Social Insects

George F. Oster and Edward O. Wilson

"Here is a grand evolutionary puzzle, tackled in this book with a flair and boldness. . . . The book is worth reading simply as an overview of the natural history of social insects. . . . Without doubt [the authors] have created some mighty and fascinating problems where before there were only ants."

— *John H. Lawton, Science.*

#12. Cloth, £11.00. Paper, £4.15

The Dynamics of Arthropod Predator-Prey Systems

Michael P. Hassell

"A lucid, clearly illustrated and eminently readable account. . . . [It] is a most welcome exposition and summary of the current position in a rapidly developing aspect of ecology to which the author himself has been a major contributor. . . . This book will undoubtedly be the standard text for both students and research workers in this field for some time to come."—*A.F.G. Dixon, Nature.* #13. Cloth, £9.00. Paper, £3.90

Some Adaptations of Marsh-Nesting Blackbirds

Gordon H. Orians

The variety of social systems among the New World blackbirds (Family Icteridae) and the structural simplicity of their foraging environment provide excellent opportunities for testing theories about the adaptive significance of their behavior. Here Gordon Orians presents the results of his many years of research on how blackbirds utilize their marsh environments during the breeding season. #14. Illus. Cloth, £10.40.

Paper, £4.60

Forthcoming: Summer 1980 Evolutionary Biology of Parasites

Peter W. Price

In spite of the fact that parasites represent more than half of all living species of plants and animals, their role in the evolution of life on earth has been substantially underestimated. Here, for the first time within an evolutionary and ecological framework, Peter Price integrates the biological attributes that characterize parasites ranging from such diverse groups as viruses, bacteria, protozoa, and fungi, to helminths, mites, insects, and parasitic flowering plants. #15. Circle No. 03 on Reader Enquiry Card

Oxford Books for Students

Problems and Solutions in Logic Design

D. Zissos

This book makes easy and reliable logic design techniques available to those with no specialist knowledge of mathematics or engineering: the emphasis throughout is on optimal, rather than strictly minimal designs, which have become less important with the availability of integrated circuits. For the second edition the text has been carefully checked and revised. It contains a new chapter on pulse-driven circuits, and many new problems and solutions. Second edition illustrated £10 paper covers £4.95

Engineering Mechanics

J. M. Prentis

This textbook provides a complete account of vector mechanics for the absolute beginner, assuming only a knowledge of elementary calculus, while maintaining the interest of the reader with previous experience by setting the exposition firmly in the context of engineering. It covers all the basic mechanics a degree student needs to know. The coverage of principles is comprehensive; applications are selective, with emphasis on the relation of principles to practical situations. £15 paper covers £6.95
Oxford Engineering Science Texts

Lectures on the Electrical Properties of Materials

L. Solymar and D. Walsh

These lectures stress the fundamental ideas relevant to the understanding of the electrical properties of materials. The topics are selected so that the operation of devices having applications (or possible future applications) in engineering can be explained. The mathematical treatment is kept simple, and topics that the student finds difficult to follow are carefully explained. For the second edition the text has been revised and updated throughout. Second edition £14 paper covers £6.95

Electronics for Technicians

R. Hamilton

This book introduces students to the electronics principles used in light-current electrical engineering with particular relevance to communications and industrial electronics. It then develops these principles to the level needed for Technician Certificates and Diplomas in a range of specialisms in electronics and communications engineering, covering the objectives developed for this purpose in the TEC standard units at Levels II and III. £12.50 paper covers £4.95
Electrical and Telecommunications Technicians Series

Coulson's Valence

Revised by Roy McWeeny

This well-known textbook had an enormous impact on chemistry when it was first published in 1952. It has now been completely revised and includes exercises, discussions of recent molecular-structure calculations, treatments of chemical reactivity theory, Woodward-Hoffmann and Evans-Dewar rules, expanded sections on the solid state, and a simple introduction to semi-empirical self-consistent field theory. SI units are used throughout. The book is written for chemists, and every effort has been made to preserve the breadth, simplicity, and clarity of the original. Third edition £17.50 paper covers £8.50

Principles and Problems in Physical Chemistry for Biochemists

Nicholas Price and Raymond Dwek

Many of the improvements incorporated in this new edition of this textbook have been based on comments and suggestions from users of the first edition, published in 1974. Chapters 1 and 10 have been completely rewritten; there is a new chapter on macromolecules and a new chapter on ultra-centrifugation. Twenty new figures have been added. Second edition illustrated £8.95 paper covers £3.95

Graphs and Networks

Bernard Carré

This book presents the basic results and techniques of graph theory and network flow theory, with strong emphasis on their applications and algorithmic aspects. It is suitable for final-year undergraduate and graduate students in mathematics, computer science, engineering, and operations research, and it will also be of interest to professional workers in these fields. The presentation is informal but systematic, and all the results given in the body of the text are justified. £14 paper covers £7.50
Oxford Applied Mathematics and Computing Science Series

Energy in the Developing World

The Real Energy Crisis

Edited by V. Smil and W. E. Knowland

Developing countries are the ones facing a real and deepening energy crisis. 'Crisis' for the Western world may mean just a reduction of predominantly wasteful practices and a lowering of expectations, but in the Third World the energy crisis is a matter of economic survival. This book of readings provides a comprehensive review, analysis, and summary of energy in the developing world. £15 paper covers £6.95

Oxford University Press

In *Geothermal Energy*, the author touches on every side of the subject. He is clearly an enormous enthusiast and it is his enthusiasm that carries the reader through the book. Indeed in some ways it may be viewed as part handbook and part evangelical tract for the cause of geothermal energy!

The book contains 357 pages of which about 60 are devoted to the general nature of geothermal areas and their geological setting, about 30 to geothermal exploration and drilling, about 160 to the techniques of exploitation and heat extraction at the surface, and about 30 to possible and actual applications of geothermal energy. The remainder is taken up with the index and bibliography (together 25 pages), wide-ranging discussions of problems of pollution, future patterns of world energy usage, and a host of other topics.

There is at present no other single book available with the scope of the present volume, although much of the material is to be found dispersed in an intractable diversity of technical publications. For this reason, if for no other, the book is a valuable one and will be widely used. The author adopts a no-nonsense, down-to-earth, practical approach to the subject which in places is excellent, but

occasionally leads to inaccurate oversimplification. He is at his best when discussing the practical problems and techniques of geothermal field exploitation. Elsewhere he may be idiosyncratic (for example, on page 46, "meteoric waters . . . is merely a 'snob' term for rainwater" — apparently connate water is acceptable); imprecise (for example, on page 85, "... temperature rises less rapidly than depth increases."), or even misleading (on page 44, "... and because of gaping cracks penetrating deeply into the mantle . . ."). This reviewer also feels that there is little point in devoting several pages to fanciful calculations of the total heat content of the Earth, even if the author does at the end emphasise that they are irrelevant to any assessment of exploitable geothermal reserves.

This is a valuable contribution to the literature of the subject. It should be on the shelves of scientific libraries. Its strength and weakness is that it is written by a slightly breathless, uninhibited enthusiast who perhaps oversells his product. □

How to put your laboratory in order

R.C. Holloway

Laboratory Organization and Management. By F. Grover and P. Wallace. Pp.241. (Butterworth: Sevenoaks, UK.) £5.95.

To many readers of this volume, the thought that they are 'managers' may well be anathema, yet, whether we like it or not, laboratories will no doubt become more organised, like most other institutions. The authors press the point that good management (but not bureaucracy) is a deciding factor between a successful and a poorly organised laboratory. In the present financial climate no doubt this is relevant.

Two chapters, on laboratory planning and service departments, encompass a wide range of subjects in a comparatively short space. There are many practical and useful hints but one is left with the distinct feeling that one has passed over rather too much, too quickly. Certainly, the style tends towards the turgid, with lists sometimes posing as sentences.

Most of the rest is devoted to the fine detail of management. Nearly 30 pages are concerned with the selection and management of staff, from the moment a vacancy

occurs until the time when the appointee leaves the establishment. Choosing the right applicant is undoubtedly a critical matter and mistakes are often made through inexperience, but this chapter reads rather like a miniature course for personnel officers. Store management and laboratory administration are followed by management technique and function. Here we are introduced to forecasting, planning, organising, motivating, controlling and communicating, in considerable detail. As would be anticipated from the authors, the chapter on safety is a model survey of safety organisation and the hazards involved.

Of errors and omissions there are very few. A reference to Dr Hughes' booklet (p.145) on *Design of Radioactive Laboratories* refers to "ionic" instead of "toxic" substances and there is a strange juxtaposition of litres per hour and gallons per day on p.27. A word of warning on present doubts about the safety of biological recirculatory cabinets (p.174) would not have been amiss.

A wealth of material based on the authors' combined experiences is here available for all who wish to embrace the doctrine that management will prevail in the laboratory. So it might, but whether it will lead to better (and happier) laboratories remains to be seen. □

Biological NMR

Henry Rattle

Biological Applications of Magnetic Resonance. Edited by R.G. Shulman. Pp.595. (Academic: New York and London, 1979.) \$29.

BIOLOGICAL NMR has now reached the stage at which a burgeoning literature provides considerable problems both for those already in the field and for those hoping to enter it. The time is clearly ripe for good review articles, and if these articles are to be of maximum use they must be thoroughly up to date, critically selective in the literature reviewed and accessible to the reasonably knowledgeable but non-specialist reader. All of these requirements are admirably met in the volume under review, but in addition the editor has imposed a pleasingly practical direction on his contributors; for example, the lone article on EPR studies concludes with some brief notes on experimental design for biological materials, and that on ³¹P NMR in living tissue contains useful graphs of the pH-dependence of the chemical shifts of inorganic phosphate as well as design details of the special apparatus used in the experiments. An article on proton nuclear Overhauser effects begins with a very clear and minimally mathematical description of the nuclear Overhauser phenomenon, while one on the use of model compounds in the interpretation of the NMR spectra of haemoproteins starts with a clear table of the oxidation and spin states of iron and a brief qualitative introduction to the theory of hyperfine shifts in paramagnetic systems. Such concern for the non-specialist reader greatly enhances the usefulness of the book.

In all, the volume contains eleven articles averaging some 45-50 pages each. In addition to those already mentioned, they include reviews on hydrogen-bonded proton exchange and its effect on nucleic acid NMR spectra, on nucleic acid structural studies, drug-nucleic acid complexes, anti-body binding sites, multinuclear NMR of the structure of alkaline phosphatase, and the NMR of catalytic groups of serine proteases and of living *Escherichia* cells. All the authors are of high reputation and long experience in biological NMR, and the standard of articles remains high throughout. The volume is reasonably priced by modern standards and is highly recommended to anyone with more than a passing interest in the subject. □

Long range order in solids

David Sherrington

Long Range Order in Solids. By R.M. White and R.H. Geballe. Pp.409. (Academic: New York and London, 1979.) \$39.50.

THE most obvious example of long range order in solids is the periodic arrangement of atoms which makes up the crystalline state. More generally, however, the concept pervades most of condensed matter physics at low enough temperature. Two other classic manifestations are ferromagnetism and superconductivity, the former relatively easily envisaged as long range order of spin orientation, the latter involving a more subtle order in momentum space. This book is an overview of the whole subject.

There is much common ground among different examples of long range order if one knows how to look. An appreciation of the universality is invaluable in using experience in one area to yield insight in another. One aspect of the book is a discussion of these common features, such as the concepts of order parameters, phase transitions and critical phenomena, the role of symmetry, excitations and so on. The main difference from earlier texts lies, however, in the wealth of experimental data used to illustrate and develop these ideas. Indeed, it is the authors' expressed belief that "a great deal can be learned by looking carefully at experimental data, and that the experience of doing so will develop judgement and intuition". Further believing that "clues to entirely new phenomena are often buried in existing data", they have presented a plethora of data, primarily, but not exclusively, taken from examples in magnetism, superconductivity and charge density wave ordering; within these fields it is difficult to find a topic which has not been touched upon. To complement this data compilation a substance index is included. Unfortunately, however, some potentially useful tables, while indexed under individual materials, are not indexed under the relevant generic names.

The stated level of the book is intermediate between a postgraduate course and a research seminar, and indeed this is about where it lies. Without a reasonably solid base in solid state physics and statistical mechanics the reader would find himself floundering quite often. Elementary many-body theory would be an asset, as also some appreciation of invariants, but one could manage without them. The other essential requirement is determination, because the cover (and often the style) is encyclopaedic but the book seems designed to be read from start to finish rather than

delved into. The student who completes the course will certainly have a broad knowledge at the end. He must, however, be prepared to dig into the research literature to pursue further any individual topic. He will be assisted by the references, which are very up-to-date (several 1978 references).

The book starts by introducing the general concepts of long range order, followed by phenomenological theories of phase transitions and excitations. It then discusses the mechanisms (real and hypothetical) leading to ordering in superconductors and magnets, and the experimental techniques available for probing them. Systematics of long range order in magnetism and superconductivity are followed by discussion of impurity effects and the coexistence of different types of order. In discussing impurity effects there is a divergence from the main subject to that of the formation of local moments in metals and the Kondo effect. Finally, there are chapters on domain structure and inhomogeneous phenomena and on long range order in amorphous and granular materials, these last being very active subjects of current research.

There is sometimes an uneasy mixture of

generality and detail, of different and sometimes inconsistent levels of assumed background knowledge, and of exact and approximate results. I consider it particularly unfortunate that in a book of this type and level approximate results are not always clearly labelled as such. I recommend caution to readers insufficiently experienced to distinguish them.

Overall, the authors have achieved their objective of demonstrating the generality of the concept of long range order, of outlining its language and tools and of showing the importance to its development of the analysis of experiment. This should be useful to a student who has a good basic foundation but lacks breadth. Whether the authors' hope that their organisation of theoretical concepts and experimental manifestations will "enable the reader to make associations which will lead to new ideas" remains to be seen. Let us hope that if it does the new discoverer will let them know. □

David Sherrington is Reader in Theoretical Solid State Physics at Imperial College, London, UK. His research interests cover several aspects of condensed matter physics in which cooperative effects are central and long range order a common consequence.

A botanist's what's what

S.M. Walters

Elsevier's Dictionary of Botany 1. Plant Names. By P. Macura. Pp. 580. (Elsevier: Amsterdam and New York, 1979.) \$109.75; Dfl. 225.

THE publication of a new polyglot glossary of botanical words is an event of some importance for librarians and others who face the problems of information retrieval for pure and applied botany. This handsome new volume by Paul Macura of the University of Nevada gives the equivalent in English, French, German, Latin and Russian of more than 6,000 plant names, and a companion volume dealing with terms of a more general nature (excluding Latin) is in preparation.

The Preface claims a unique place in botanical literature for the book, apparently ignoring the existence of the *Botanical Dictionary: Russian-English-German-French-Latin* by N.N. Davidov published in Moscow in 1960. It is true that Macura's dictionary deals exclusively with plant names, for which there are more than three times as many entries as in Davidov; but the proof of the

pudding is in the eating, and in a random test of five English vernacular plant names, birch, bracken, honey fungus, lucerne and maize, Davidov scored four correct or tolerably correct answers, against only three for Macura. Both signally failed to recognise that the English (as opposed to American) word for the crop *Medicago sativa* is 'lucerne', not 'alfalfa'; and Macura seems to think that the English name for *Pteridium aquilinum* is 'adderspit', though he recognises 'bracken' for the western North American var. *pubescens*.

The decision to include in the primary alphabetical listing of English names a large number of "adjectival vernacular names" seems difficult to justify. It enormously expands the book with relatively little gain, and omissions and inclusions seem to be quite arbitrary. Indeed, a more ruthless selection of original material could have produced further economies by eliminating, for example, 'goldmoss' which immediately precedes, and refers directly to, the next entry (No. 2553). The verdict must be that the dictionary is useful, but that it could have been more carefully checked; it could also have been much more compact and therefore cheaper. □

S.M. Walters is Director of the University Botanic Garden and Fellow of King's College, Cambridge, UK.

OBITUARY

R. B. Woodward, 1917–1979

THE sudden death of Robert Burns Woodward of Harvard University on 8 July 1979 at the age of 62, marked the passing of one of the most important organic chemists of this century.

In offering the following account of some aspects of Woodward's achievements the main scientific emphasis will be on his contribution to chemical syntheses. I will leave to others a discussion of the celebrated Woodward-Hoffmann rules. It would, however, be wrong to undertake this exegesis before giving some idea of Woodward's impact on those — and they were hundreds — who came in contact with him.

Woodward's impact on his associates came first from an awesome command of the whole of organic chemistry, ranging from the incredibly complex mass of interrelations and transformations which chemists had produced while unraveling the molecular architecture of complex natural products, such as quinine, morphine or strychnine; to the ever more rapidly accumulating data on the course of chemical reactions and their theoretical basis; extending finally to the multitude of transformations, not excluding the most obscure or esoteric, which might be put to use some day in the rational construction of a complex structure.

Woodward's great strength was his conviction, which he conveyed to his associates, that chemical problems should be placed in a rigorously rational framework; leaving no room for fuzziness, for half understood data, for any but the most mercilessly logical deduction, whether dealing with the structure determination of an unknown natural product, or of an intermediate in a synthetic sequence. Woodward's intense commitment to organic chemistry was allied to the conviction that there must be underlying order beneath what often seemed a chaotic mass of unrelated observations. This approach showed fruit very early (1941) in the well-known "Woodward rules" which provided a generally useful correlation of important structural features of α , β -unsaturated ketones with their ultraviolet absorption maxima.

This early recognition of the importance of the informed application of physical methods to structural problems led Woodward to give a major role to the emerging tool of infrared spectroscopy in his rigorous deduction of the β -lactam structure of penicillin (1944–45). This, and the later conclusion that the vast amount of the existing strychnine chemistry demanded revision of the accepted structure to a different one, now known to be correct, are early examples of

Woodward's mastery of this highly intellectual form of detective work. His skill in presenting his conclusions in a dramatic and lucid style makes his accounts of the elucidation of the structures of strychnine and, *inter alia*, of the tetracyclines or tetrodotoxin fascinating and highly rewarding reading. This is true even today, in spite of the fact that such problems have largely been taken away from chemistry by advances in X-ray crystallography.

The faith in an underlying rational structure showed itself also in Woodward's brilliant use of the "curved arrows" which Robinson's genius had earlier introduced into organic chemistry, to indicate the breaking and forming of bonds, and which have become an essential conceptual tool in visualizing the path from reactants to products. It was Woodward, more than anyone else, not excluding Robinson himself, who showed that Robinson's curved arrows could be submitted to rigorous logical constraints, and that, when they were thus used, they would greatly assist, not only in systematizing observed reactions, but also in predicting which reaction might be possible, and which unlikely. An early example (1948; 1950) of Woodward's command of this tool can be found in his unraveling of some baffling molecular transformations in the Santonin series.

There is one area of chemistry which is most uniquely the domain of organic chemistry, and that is molecular architecture, or synthesis. As chemists entered the twentieth century, the very small number of reactions which might be useful in reaching the complex targets represented by natural products such as cocaine, quinine, morphine or the steroids, coupled with a general lack of knowledge

of ways to control stereochemistry, the three dimensional arrangement of atoms in space, made the challenge of total synthesis of most natural products as formidable as it was exciting. Nevertheless, some beginnings were made: Willstätter synthesized tropinone, the parent of cocaine, around 1900. This was a work of genius, given the state of development of chemical synthesis at that time, but the labored nature of the synthesis also served to emphasize the enormous problems to be faced by would-be molecular architects.

It must have been as important psychologically as it was chemically startling, therefore, when Robert Robinson's famous construction of tropinone burst upon the chemical world in 1917. Willstätter then succeeded in transforming tropinone into cocaine in 1923: the possibility of other complex total syntheses could now be contemplated. Some progress on methodology came from "partial synthesis," the transformation of one natural product into another (e.g. ascorbic acid from hexoses by Haworth, and by Reichstein, in 1933); the forbidding, though achiral, haemin was put together by H. Fischer in 1928 by a combination of steps which must have convinced any would-be practitioner that witchcraft must play a large part in a successful synthesis. Probably the greatest achievements in the decade preceding the second World War were the synthesis of dihydroquinine by Paul Rabe in 1931, and that of equilenin by Bachmann in 1939.

It is on that stage that R. B. Woodward made his dramatic entrance with the announcement of the synthesis of quinine (with W. E. Doering) in 1944. The synthesis commanded worldwide attention because of the burst of publicity (front page of the *New York Times*: "Second Answer to Japan") (the first, being, supposedly, synthetic rubber) which propelled Woodward, then twenty-seven, to a limelight which he did not altogether dislike. Dramatic as it may have seemed to the press, Woodward's quinine synthesis closely followed the scheme laid out by Rabe in his hydroquinine synthesis. It shares with that early synthesis an almost total lack of stereochemical control. And yet, it is of great importance because, in connection with the construction of a piperidine derivative, it introduced what I believe to be one of Woodward's most important contributions to the strategy of complex synthesis: the formation, manipulation and eventual cleavage of rings of carbon atoms as a method of construction of acyclic elements. This approach led to a considerable simplification of the route to the target structure, since it allowed carrying

functional groups in a latent, less reactive form: in the piperidine precursor of quinine, an eventual ϵ -aminoheptanoic acid system is constructed by the cleavage of a 2-methylcyclohexanone, a chemically less reactive, and thus more easily controllable system.

The modern era of concern for stereochemistry started in the period 1950-1955, a period which saw the development of stereospecific, or highly stereoselective, syntheses of morphine, cantharidin, cortisone, cedrol and strychnine. These syntheses were all carried out without taking advantage of the enormous help, just becoming available, of Barton's principles of conformational analysis, but they are important because they represent the first successful efforts to take stereochemistry explicitly into account during the process of synthesis planning. This may seem an obvious prerequisite to a successful synthesis, but one need only read the highly imaginative, though largely inconclusive, series of some sixty papers on steroid "synthesis" by Robinson and his collaborators to see the staggering efforts which could be made to reach synthetic targets (steroids in this case), without any concern for the need to control the relative arrangement of the relevant atoms in space. When one considers that without such control, the connectivity implied by the two-dimensional structure of cholesterol represents 256 different substances, only one of which is cholesterol, it is no wonder that these efforts, brilliant as they sometimes were, remained largely abortive.

Although Woodward's 1951 steroid synthesis was only partially stereoselective in contrast to the cortisone synthesis (by L. H. Sarett) referred to above, it was nevertheless highly influential because it against used the structural simplification made possible by a temporary ring: a cyclohexene ring serves as the source of the steroid D-ring via its cleavage and cyclization to a more functional cyclopentene aldehyde. One also sees here an illustration of another important principle of many Woodward syntheses: the carbon framework is constructed as rapidly as possible, leaving some function (e.g. double bond) which will allow eventual structural adjustments.

It is with the synthesis of strychnine, in 1954, that Woodward began a series of classically elegant syntheses which have not yet been surpassed. In addition to strychnine, they are those of reserpine (1956), of chlorophyll (1960) and of the "western half" of vitamin B₁₂ (1972). In the strychnine construction, the ubiquitous ring element, placed in the α -position of the indole ring of tryptamine, is a dimethoxybenzene ring which is here a latent 1,4 butadienedicarboxylic (muconic) ester system, in a much less reactive form. Before that transformation, however, that same ring is brilliantly used to ensure that an intramolecular cyclization via an

iminium salt occurs at the β -position of an indole ring. The synthetic use of a dimethoxybenzene ring as a precursor of a muconic acid illustrates an aspect of the Woodward mastery which has been referred to previously: the cleavage of an ortho-dimethoxybenzene to a muconic acid had been stored in Woodward's memory since he had noticed its use by Speyer in the degradation of codeine. He was able to recall it just when it would be most dramatically useful.

In the synthesis of strychnine, details of oxidation states were consciously held in the background because of the great structural simplification thus allowed in the construction of the framework. This approach is further refined in the next great synthesis, that of reserpine, in which full and impressive use is made, for the first time, of Barton's conformational principles. In that synthesis, we have, once again, the use of a cyclohexene ring as a surrogate for an eventual aldehyde-ester. We also see here the dramatic simplification produced by the use of a double bond as the precursor of the monomethyl ester of a 1,2-glycol. There were, *a priori*, four possible such systems which might result from the cyclohexene double bond. Woodward had acquired, by that time, extraordinary confidence in his ability to find some way to make molecules dance to his tune: he felt that something might well happen during the synthesis, which would solve this potentially vexing problem. He was not disappointed. Only someone with Woodward's ability to deduce structures from a combination of limited spectral data and mechanistic insight could possibly have capitalised on the remarkable chemical events which provided a solution to the problem. Seldom has it been more true that "chance favors the prepared mind."

Chlorophyll and the "western half" of vitamin B₁₂ will end this broad sketch. In the synthesis of the former, it is still notable that a problem in producing the required regiochemistry was solved by selecting an aminoethyl group as precursor of an eventually required vinyl substituent, and using it in temporary ring formation with a pyrrole aldehyde. Again, the very difficult problem of introducing the two so-called "extra" hydrogens specifically in one of four pyrrole rings was solved, in a unique manner, by a sequence involving cyclization followed by cleavage.

Finally, when we come to the B₁₂ synthesis of 1972, we are treated to a pyrotechnic display of appearing and disappearing rings which are used here to achieve control of almost all the asymmetric centers in the molecule. A propionic acid chain arises from the remains of an anisole ring, and another one from a temporarily constructed cyclohexene. A δ -ketoacid originates from the cleavage of a cyclopentene; an amino acid system is born from a cyclopentanone, as yet further rings make

their tightly orchestrated entrances and exits from the B₁₂ stage: a grand final tribute to the power of this approach to synthesis.

I referred at the very beginning to the great impact that Woodward had on all who associated with him. This was nowhere more obvious than in the celebrated "problem seminars" in which Woodward was always willing to take on all those who cared to match wits and deductive skills with him. It was not just the graduate students and postdoctoral associates who benefitted from contact with Woodward's logical approach to all chemical problems: an impressive number of papers by celebrated chemists all over the world (Arigoni, Bartlett, Barton, Bloch, Djerassi, Eschenmoser, Gates, Inhoffen, Jeger, Klyne, Prelog, Wilkinson, Winstein, Witkop. . .) have Woodward as a coauthor, obvious testimony to the insights that were gained by discussions with him.

Woodward would not have been human had he not enjoyed the attention he commanded. He relished keeping audiences enthralled for hours with a lecture in which he obviously savoured highlighting the already brilliant work he was describing by using meticulously drawn formulas, dramatically enhanced by the controlled use of colored chalk, further to emphasize the image of one in total command of his environment. He was not above playing along with the sensationalism of the media: "That is what the public wants of its heroes"; and he had no doubt that he had earned the right to special recognition at every level. One anecdote, perhaps, sums up the view he had of his rightful place in the world: A new guard at Harvard had just told Woodward that his (blue) car could not be left where he had placed it. "Why is that?" said Woodward. "Your name is not on the list," said the guard. "It isn't?" said Woodward, turning back toward the guard without stopping, "well . . . put it there!" One thing is certain, Woodward's place in chemical history is permanently reserved.

Gilbert Stork

G.S. Forbes

GEORGE SHANNON FORBES, Emeritus Professor of Chemistry at Harvard University, died on 24 June 1979 in his home in Cambridge, Massachusetts.

Born on 17 March 1882 in Boston, Massachusetts, Forbes' interest in science was awakened at the age of eight, by a lecture on pendulums given by his father, George Fairfield Forbes, who was a pioneering teacher of experimental science at the prestigious Roxbury Latin School. But when young Forbes graduated from that same school he aspired to a career as a professor of classics. During his sophomore year at Harvard College, he reports, in a course on qualitative analysis the

challenge of numerous "diabolical mixtures . . . aroused my combative instincts, and provided real excitement . . . Gradually the classics were supplanted by a new enthusiasm. Then followed a truly decisive event. Professor Charles R. Sanger told me that next year's class would be larger than usual. Would I serve as assistant without stipend? Of course I said 'Yes,' and so, not long after my eighteenth birthday, I became a duly appointed officer of instruction in Harvard University, continuing on through senior year . . . Ten years later, this adventure had a direct influence on my fortunes. When Professor Sanger's health became impaired, I was asked to collaborate with him. Upon his death, I took charge of qualitative analysis, and thus my feet became planted upon the academic ladder."

By that time Forbes had long since passed from undergraduate to graduate work at Harvard. Under the direction of T.W. Richards, later to become America's first Nobel laureate in the sciences, Forbes completed in 1905 a doctoral thesis on the electrochemistry of amalgams. He then went on with Richards to a revision of the atomic weights of nitrogen and silver. The keystone of this endeavour was a meticulous redetermination of the exact weight of pure silver nitrate yielded by one gram of pure silver, and the result thus obtained still stands unchallenged (good to 0.002%). But this notable first was also Forbes' last investigation of atomic weights. Most of his nearly 100 research publications deal with solution physical chemistry, especially electrochemistry, and with photochemistry, in which field he was an American pioneer.

Forbes' life and career were wholly centered on Boston and Cambridge Massachusetts. To be sure, he spent 1906-07 at the universities of Leipzig and Berlin, followed by two years as associate in chemistry at Bryn Mawr College. But in 1909 he returned as instructor in physical chemistry to Harvard University, and here he stayed to become Professor in 1926, Chairman of the Chemistry Department in the difficult years 1944-47, and Emeritus Professor in 1948. Even then Forbes' academic career continued for 8 years more Northeastern University and, still persevering as a consultant to chemical industry, inuing as a consultant to chemical industry, he continued laboratory work with his own hands until the age of 90. Triumphant over the hazards besetting the experimental chemist, he was at 97 the oldest living graduate of Roxbury Latin. He outlived his cherished wife of 60 years, *née* Marie Louise Hersey, but is survived by a son, a daughter, and four grandchildren.

Born into a family where father, mother (*née* Elizabeth Shannon), aunts, and uncles were all teachers, Forbes came naturally to that vocation. His teaching career spanned 60 years and some 9000 students. A highly-organized lecturer who wrote everything out in a well-ordered display on the black-

board, Forbes was also a willing spontaneous commentator on the illuminating aberrations of the innumerable lecture experiments he dextrously produced. He was in 1951 the deservedly first recipient of the James Flack Norris Award for outstanding achievement in the teaching of chemistry.

Forbes was a New Englander through and through: sturdy, spare, independent, reserved, and patient. But beneath the somewhat austere exterior lay abundant dry wit, and a human warmth that engaged many friends. An attractively multi-dimensional person, Forbes was a photographer of professional competence, an energetic hiker and climber (long the faculty adviser of the Harvard Mountaineering Club), and an avid musician who lent his (double bass) voice to many local choruses. His high sense of responsibility found expression in a lifetime of devoted service to his science, his Department, his University, and his Church. His was a New England life of little showiness but admirable substance.

Leonard K. Nash

Sir Frank Fraser Darling

THE death of Sir Frank Fraser Darling on 22 October 1979 at the age of 76 will be greatly regretted by naturalists and wildlife conservationists in many parts of the world. Although he only came to wide public notice in Britain when he gave the 1969 Reith Lectures, he had made outstanding contributions to the understanding of wild animals and of the countryside over a period of some 50 years, and his counsels were much sought after in America and elsewhere in the 1950s and '60s, when his own countrymen paid less attention to his opinions.

He started work in 1924 as an agriculturalist. After three years on the staff of the Buckinghamshire County Council he went as a research student to the Institute of Animal Genetics in the University of Edinburgh. He was appointed Chief Officer of the Imperial Bureau of Animal Genetics in Edinburgh in 1930, under the late Professor F.A.E. Crew, and he remained in that post until 1933. He then gave up this urban, academic life, and began his work, often under conditions of considerable austerity, in the highlands and islands of Scotland. He held Carnegie and Rockefeller research fellowships, and was Director of the West Highland Survey from 1944-50, but this was a precarious existence with little of the security scientific workers expect today. However, he was able to spend his time in the field really getting to understand the conditions of his harsh environment.

During this period he wrote many books such as *A Herd of Red Deer* and *A Naturalist on Rona*, vividly describing his

observations and his experience. His *Bird Flocks and the Breeding Cycle* initiated a new field of research. These books had a considerable appeal to other naturalists and to discerning scientists, but were dismissed as too "popular" by the educational establishment, and so did not receive the recognition his admirers felt they deserved. He was bitterly disappointed at the reception given by "the authorities" to his West Highland Survey. His apparently eccentric behaviour and unconventional way of life (something which would be thought normal today) also prevented him from being properly appreciated as an observer and an ecologist in academic circles. At a time when laboratory studies of animal cells or isolated organs were considered more scientific than those involving whole animals in the wild, and when even meticulous observation was considered inferior to experimentation, it is not surprising that he felt he was not properly appreciated.

He did return to academic life for a few years when he was appointed Senior Lecturer in Ecology and Conservation at Edinburgh University in 1953 at the age of nearly 50. He was also invited by the Nature Conservancy in Britain, then a young and developing organisation, to advise them in their studies on Red Deer. This work, and his earlier observations, enabled the Conservancy to introduce a proper management policy particularly to the island of Rhum, where within the National Nature Reserve populations of deer were maintained at optimum levels by a careful culling policy. However, Fraser Darling increasingly found that his views were being taken more seriously in the United States of America, and in 1959 he accepted an invitation from Dr Fairfield Osborn to become Vice President of the Conservation Foundation in Washington DC. His studies of the caribou in Alaska with Dr Starker Leopold, and of the larger mammals in Northern Rhodesia and other African territories did much to consolidate his international reputation.

While in the United States he was impressed with the work done there in setting up National Parks, and he was critical of other countries, including his own, for their slowness in following the American example. However, he praised the British Nature Conservancy for their work, with limited resources, and particularly for establishing several valuable reserves in Scotland.

As already indicated, it was not until 1969 that Britain recognised his contribution to conservation. 1970 had been designated European Conservation Year, and plans to that end were being made by a committee under the patronage of HRH Prince Philip. It was suggested that the 1969 Reith Lectures of the British Broadcasting Corporation should be devoted to some suitable ecological topic, and that they should act as a curtain raiser.

Fraser Darling was an inspired choice as the speaker. He took as his title *Wilderness and Plenty*. The lectures came at the right time, and the lecturer made the most of his opportunity. The public, as distinct from the scientific community, had just learned to use the word "ecology", and to be worried about the future of the environment. The impact of the lectures was considerable, and Fraser Darling was accepted, particularly by students, as a prophet. His status was also radically changed and, somewhat to his surprise, he found himself very much a part of the Establishment. The Queen honoured him with a knighthood, and he was in demand to join the most prestigious Quangos.

Thus from 1970 to 1973 he served on the Nature Conservancy, and in 1970 he was one of the first selected for the Royal Commission on Environmental Pollution. However, he was not seduced by his acceptance by the authorities, and still continued to speak his mind on environmental problems. He was in great demand as a speaker and a writer, but unfortunately ill health prevented him, particularly in recent years, from playing an active part in public life.

It is difficult to assess Fraser Darling's contribution to science at this time. His books show his deep but unsentimental feeling for the countryside and for the animals which inhabit it. He was able to communicate to the public (as in the Reith Lectures), and although this very ability aroused disapproval in some (? envious) academics, it enabled him to make a unique contribution to conservation. However, many of his colleagues, even those who admired him most, did not consider him to be an outstanding ecologist in the academic tradition, and it is not difficult to pick holes in some of his work. Nevertheless he was a leading figure who followed in the British tradition of the study of scientific natural history, and we can take comfort from the fact that at least for the last years of his life this was realised by his countrymen.

Kenneth Mellanby

C.S. Hallpike

DR CHARLES SKINNER HALLPIKE, CBE, FRS, FRCS, FRCP, who died on 26 September 1979, aged 79, was a neuro-otologist of international renown. He was the pioneer in that field and is respected as such in every country of the world.

Although an experienced physiologist and pathologist, Dr Hallpike's special interest was in the relationship of experimental observation to clinical problems. His ability for meticulous work and great clarity of thought enabled him to marshal facts and produce scientific papers in stylish and fluent prose. He is best remembered for his original description of the pathology of Ménière's disease and for the development of a caloric test technique which has, over the years, withstood the

test of time and is now universally accepted.

Dr Hallpike was educated at St Paul's School and graduated in medicine at Guy's Hospital, London in 1926 where he was Entrance Scholar in Arts and Beaney Prizeman in Pathology. His interest in the ear began when he was House Surgeon to the aural departments of Guy's Hospital and Cheltenham General Hospital from 1924 to 1927. Thereafter, as Bernard Baron Research Fellow at the Ferens Institute of Otolaryngology, Middlesex Hospital, the publication of a number of papers concerned with the electrophysiology of hearing resulted in his being awarded the Duveen Travelling Studentship, University of London, 1930 and the Rockefeller Travelling Fellowship 1931, when he studied with Witmarck in Germany and in the University of Philadelphia, USA. His high standard of scholarship received further recognition in the awards of the Foulerton Gift Research Fellowship, Royal Society (1937-40) and Gamble Prize in 1934, William J. Muckle Fellowship, University of London, 1941 and Dalby Prize, 1943.

In 1942 he joined the scientific staff of the Medical Research Council at the National Hospital, Queen Square, London where his power of organisation and administration resulted in his appointment as Aural Physician and Director of a newly established Otolaryngological Research Unit at the hospital. Here, with his awareness of the close liaison which should exist between laboratory and clinic in the solution of problems throughout the field of otology, his work became directed towards establishing this link to the great advantage of both. In association with experts in numerous allied disciplines including physics, physiology, biochemistry, histology and clinical investigation, a series of classic publications issued from his unit emphasising the importance of the adoption of quantitative methods in both laboratory and clinical studies of the ear.

The practical outcome of this work included the Medresco hearing aid, the peep-show technique for measuring deafness in young children, recognition of the diagnostic significance of loudness recruitment in sensori-neural deafness and the definition of a number of clinical and pathological entities hitherto grouped together as 'aural vertigo.' An improved technique for temporal bone microtomy was developed, a rotating chair, a head lamp for aural surgery and an ear microscope. Further studies contributed to knowledge of the heredity of labyrinthine disease and the biochemistry of the labyrinthine fluids. At a later stage the narrow-band masking technique for bone conduction audiometry was evolved and an electro-nystagmographic technique, the diagnostic significance of which is still increasing.

Dr Hallpike's unit gained international recognition in the awards he received of the

Gamble Prize for the second time and the Hughlings' Jackson Lectureship and Medal, Royal Society of Medicine 1947; Bárány Medal, University of Uppsala 1958; Guyot Medal, University of Groningen 1959 and the Dalby Prize (awarded jointly) in 1958. In 1956 he became a Fellow of the Royal Society and in 1958 he was honoured with a CBE.

Upon his retirement from the staff of the Medical Research Council, Dr Hallpike was appointed Honorary Aural Physician and Director of Research at the Ferens' Institute of Otolaryngology, Middlesex Hospital from 1965 to 1968. He was a member of numerous learned societies including the Collegium Otorhinolaryngologicum Amicitiae Sacrum whose Shambaugh Prize was awarded to him in 1955. He was an Honorary Fellow of the Royal Academy of Medicine of Ireland, a Fellow of the Royal Society of Medicine, being Honorary Secretary 1938, Editorial Representative 1946 to 1952 and Honorary Member of the Section of Otology 1970. He was joint Founder of the Bárány Society in 1960, a society which now has world-wide membership and is unique as being solely directed to the study of vestibular problems. Between 1938 and 1965 he was a member of the Flying Personnel Research Committee where his almost unique knowledge of the ear's functioning in health and disease played a large part in overcoming aural problems important in aviation.

Dr Hallpike had the great merit of having inspired many collaborators to engage in scientific work and his wisdom and shrewd judgement will be remembered the world over. He was the acknowledged master of his subject, albeit a hard one, a perfectionist, utterly single-minded in all he undertook. He was quick to recognise and appreciate good work, intolerant of fools but unfailing in giving due credit to his co-workers. The fact that the majority of his unit staff remained with him over the years, a number from its inception until his retirement, is testimony in itself to his integrity. He had enormous courage in the face of an orthopaedic disability resulting from a childhood injury which precluded many outside activities. He played billiards in his younger days and enjoyed rifle practice at Bisley for which he gained a number of awards. He played the piano and violin and was fond of classical music. He enjoyed gardening after his retirement and won prizes locally for his roses. He was a devoted family man and is survived by his wife, Barbara, and two sons.

His death is a great loss to British otology. The establishment of the Medical Research Council Hearing and Balance Unit at the National Hospital, Queen Square, under the directorship of Dr J.D. Hood, with other members of his old staff, remains a living tribute to his pioneer work.

Chemical arms: a sea of troubles

RECENTLY, the worldwide press has reported on how rumours of Soviet chemical warfare in Afghanistan have led to increased support in the US for the resumption of manufacture of chemical weapons. Europe should take note of these reports, for if US chemical weapons production does resume it will almost certainly have been endorsed beforehand by at least one European government. Prior experience suggests that such endorsement will not receive prior parliamentary debate.

For several years European members of NATO have been under pressure from the United States to reconsider their positions on chemical weapons. Existing NATO policy is that chemical weapons are to be used only for retaliation in kind within the prevailing 'flexible response' defence strategy. US officials believe that this policy requires NATO to integrate a retaliatory chemical capability much more closely into its military planning and posture than it has so far done. France and the US are alone within the alliance in possessing significant stocks of poison gas, and, although certain other member-states, such as Britain, keep themselves informed about how to use chemical weapons, the remainder do not. West Germany, in particular, has long committed itself against acquiring its own, and has declared that it will not seek access to anyone else's.

The prevalent European view has been that the threat of escalation (including nuclear weapons release) implicit in the flexible response strategy, coupled with the antichemical protection of NATO forces, provides sufficient safeguard against Soviet resort to chemical warfare. Antichemical protection is currently being upgraded, and is capable of negating the mass-destructiveness of chemical weapons on the battlefield, albeit at some cost to fighting efficiency. French and American chemical weapons are seen as a useful extra precaution to the extent that they can act as an additional deterrent — a belief which may or may not be sound.

Suggestions that the NATO chemical retaliatory capability should be expanded have been opposed on several grounds. First, such an expansion could be interpreted as a sign of diminished resolve to use nuclear weapons. Increased deterrence of chemical warfare would then have been bought at cost of reduced overall deterrence. Secondly, there would be greater returns for European security from investment in improved conventional capabilities. In addition, a new chemical armament drive would compromise the current negotiations on chemical disarmament, which in theory offer the best safeguard against chemical attack.

While many Americans appreciate such arguments, some maintain that the present state of nuclear parity now thought to exist between the US and the USSR, together with the apparent Soviet interest in chemical weapons, strengthens the requirement for a special chemical-warfare deterrent. For reasons that are not entirely clear, they believe that their existing special deterrent — in the form of the one to two weeks' supply of US chemical munitions now on hand in West Germany, replenishable from much greater American stockpiles — is insufficient. Hence the plans for a new chemical weapons factory with a projected expenditure, so it is said in the American press, of \$1,300 millions, on an output of nerve gas artillery shells, bombs and warheads.

Such a programme can make sense only if Europeans undertake, at the very least, to accept the new weapons on their soil. This is the endorsement which potential host countries will be asked, once again, to give.

There are few public signs of the way European opinion may go on poison gas. The Afghan allegations, however unsubstantiated, could be influential, succeeding as they do a whole series of others that the USSR will use chemical and even biological warfare whenever it is militarily expedient, regardless of treaty

constraints. Reports have alleged Soviet backing for Vietnamese chemical warfare in Laos and Kampuchea, expansion of Soviet chemical-weapons stocks, and Soviet violation of the 1972 Biological Weapons Disarmament Convention. Yet, as a recently published review of these different charges shows in some detail*, no solid evidence has been disclosed for any of them.

Should the allegations be true, the implications for the West would be serious. The problem is that uncertainty about them extends to government — a symptom of the generally poor state of western chemical warfare intelligence. Because there is little hard information, these reports are in fact rooted in worst-case assumptions. Capabilities are estimated by equating them with the requirements for chemical weapons set by Soviet military doctrine on chemical warfare which, though not known with any precision, is assumed to teach maximum exploitation of all battlefield target effects available from toxic chemicals. The stockpile tonnage estimates quoted recently in the US press (*Nature* 13 March, 1980) are no exception. Their belittling of American capabilities is also commonplace, compounded in this instance by a confusion of chemical weapons with poison gas: it is the latter, not the former, of which the Americans have 42,000 tons — a supply sufficient to fill up to half a million tons of chemical munitions.

Absurdly, such estimates of Soviet stocks are frequently quoted by military analysts and journalists as evidence of the intentions from which, in fact, they were deduced. Because the Soviets have an enormous supply of chemical weapons, such comment goes, they must be planning for protracted chemical warfare of their own initiation. Yet such hard quantitative information as there is, drawn mostly from sightings of Soviet depots in forward areas believed to contain chemical weapons, is equally consistent with a retaliation-only posture, similar to NATO's.

In the historical record of US and Soviet chemical warfare preparedness since World War II, there is clear evidence that the programmes of one side have driven, at least in part, those of the other. The US stopped adding to its stocks of chemical weapons in 1969; the USSR, a year or two later. It would be highly dangerous if a cycle in the opposite direction were now to be set in motion again. The chemical arms limitation talks in Geneva, which are proceeding in both a US-Soviet working group and within the 40-nation UN Committee on Disarmament, provide what is probably the only available channel of communication for resolving such uncertainties. The first priority for the West in its policy-making on chemical warfare must therefore be to keep this channel open.

Over the years the negotiations have advanced to the point where they are now turning on intricate questions of the controls that must be placed on national chemical industries, and on particular military facilities, in the interests of adequate treaty verification. These raise issues of such delicacy that negotiation can proceed only if there is mutual confidence.

If the Soviets are innocent of the chemical and biological warfare allegations against them, a new western chemical armament drive cannot fail to deepen mistrust and suspicion. Although a go-ahead for the US binary nerve-gas plans could strengthen the position from which the West is negotiating, it could at the same time destroy the basis of negotiation. While Europeans may not be able to do very much to promote chemical arms control, they may soon be in a position to kill it. □

United States

Inventorship dispute stalls DNA patent application

Is scientific history being rewritten to make research results more patentable? David Dickson reports

A PATENT application covering some of the basic techniques of genetic engineering is being held up by the US Patent Office in a dispute over whether the applicants can legally claim to be the sole inventors. The patent request has been filed jointly by Stanford University and the University of California, San Francisco, (UCSF) on behalf of Dr Stanley Cohen and Dr Herbert Boyer. It covers techniques developed at the two institutions in the early 1970s, which demonstrated for the first time the feasibility of replicating biologically-functional foreign genes introduced into a living organism.

Central to the patent application, first filed in 1974, is a paper published in the *Proceedings of the National Academy of Sciences* (70, 3240, 1973) in the preceding year, which describes the successful construction and replication of a plasmid capable of transferring antibiotic resistance into *Escherichia coli*.

In addition to Cohen and Boyer, the paper names two other authors Dr Annie Chang of Stanford and Dr Robert Helling, Associate Professor of Botany at the University of Michigan. According to the rules of the Patent Office, joint authorship means the two are considered co-inventors of the processes described.

Stanford and UCSF argue that although the research described in the paper and the patent application was built on techniques developed elsewhere, it was Cohen and Boyer who provided the creative input necessary to demonstrate their potential. They did this by conceiving and demonstrating how the techniques could be combined to create functional recombinant plasmids.

But Helling, who is not named in the patent application, disputes that his role was marginal. He has refused to sign a disclaimer, required by the Patent Office before it approves the application, agreeing that he was not an inventor of the processes described.

"I felt that we were all equal in this, and do not want to sign a letter saying that I was just another laboratory worker", he told *Nature* last week. "I was part and parcel of the whole thing; I don't feel that I should sign something that I do not believe is true."

Helling is not the only scientist who has refused to sign (although his refusal has been the most disruptive). Dr John Morrow, of Johns Hopkins University, the first author on a 1974 *PNAS* paper cited by

Cohen: forgoing royalties

Cohen and Boyer (to show how a bacterial plasmid could be used to reproduce *Xenopus* DNA), complains in particular about the secrecy which has covered the application. "I am not prepared to sign a disclaimer to a patent application that I have not seen," he says.

And there may be further disputes in store. In addition to the process patent, Stanford and UCSF are also asking protection for the plasmid developed, arguing that it was the development of this particular pSC101 plasmid that made the success of the techniques possible.

Meanwhile, patents are being granted on the processes used. Dr Roy Curtiss, of the University of Alabama, has recently been granted a patent for the techniques used to create the disabled χ 1776 strain of *E. coli* (for which both process and product patents have already been issued in the UK).

The issue has raised at least two separate arguments. The first is on the morality of granting private licensing rights to the results of research carried out on public funds. As this is currently accepted practice, most scientists feel that Stanford and UCSF are justified in seeking to benefit from research which the two institutions pioneered — particularly since the two universities stress that the patents would remain freely available to anyone who wanted to use the techniques for research purposes. And both Cohen and Boyer have agreed that royalty proceeds should go to

support research at the universities, and that neither will benefit directly.

A further difficulty arises from the clash between scientific conventions of co-authorship, and the legal implications of these conventions when it comes to claims of inventorship. The latter is a legal definition which courts have ruled is enshrined in the Constitution, but is seldom considered by scientists in determining whose name should go on a research paper. Patents can be granted for techniques whose details have been published less than a year previously, but where such prior publication has taken place, all those listed as co-authors are treated as *prima facie* co-inventors.

In the Stanford/UCSF case, all agree that the development of recombinant DNA methodologies relied heavily on discoveries made at several institutions, for example on work on restriction enzymes at Johns Hopkins University and by Paul Berg's group at Stanford, or on the functioning of ligases at the National Institutes of Health.

As Cohen puts it: "Scientific advances such as the one we have been involved in are in fact the result of multiple discoveries carried out by many individuals over a long period of time". The difficulty lies in evaluating the significance of any particular contribution.

Patent attorneys for the two universities argue that Boyer and Cohen provided the "major inspiration and direction" for the experiments described in the *PNAS* paper, and they have told Helling that, unless he signs the disclaimer — or they can convince the patent examiner by other means that he has no legal claim as an inventor — then they will seek a court order instructing the issuing of a patent, and 'deposing' him as an inventor. But a full-scale legal dispute is not a prospect that anyone fancies.

Legally-defined constraints imposed by commercial considerations are proving a problem for scientists concerned to retain the integrity of the research process.

"It is difficult to demand high standards of your students when you see some of the things that are going on", says Dr Mark Ptashne of Harvard University, who claims that colleagues are beginning to write papers and cite references. "In such a way that their patent applications are valid".

Dr Zsolt Harsanyi, who is currently heading a major study of the implications of recombinant DNA technology for the office of Technology Assessment, confirms that "in the past couple of months" scientists have begun to talk about the potential for rewriting scientific history as a "serious problem".

Some are now using this as an argument against permitting the patenting of research results at all. Others suggest that fields such as electronics and chemistry have faced such conflicts for years, and have learned to live with the consequences.

In the case of molecular biology, the learning process does not look like being a comfortable one. □

Third World science fund: promises unfulfilled

THIRTY-five countries last week pledged a total of \$36 million to a new fund being set up by the United Nations Development Programme to assist developing countries build up their scientific and technological capabilities.

The fund was agreed as an interim measure at last summer's United Nations Conference on Science and Technology for Development, held in Vienna. UNDP officials estimate that extra commitments already made increase the amount pledged to \$45.7 million; a number of other countries are expected to make additional contributions over the next few months. However, the figure reached is far short of the \$250 million which delegates to the Vienna conference, agreed should be a minimum target for the fund (contributions to which would be voluntary).

The developing countries had proposed a more ambitious financing system at Vienna, based on automatic contributions and aimed at targets of \$2 billion by 1985 and \$4 billion by 1990. But the developed countries put forward the proposal for the interim fund as an alternative. This fund is initially designed to operate for the two years 1980-81: during this period, a group of specialists will meet to decide whether the more ambitious proposal is a feasible proposition, and if so how it should be carried out.

Meanwhile plans are already being drawn up by the UNDP for allocating the money contributed to the fund. It is meant to support the implementation of recommendations agreed at Vienna, such as promoting scientific cooperation between developing countries on a subregional and regional level, and seeking to strengthen their "endogenous scientific and technological capacities".

Last week's pledging conference in New York was attended by delegates from 78 countries. Almost all said that they supported the goals of the fund, although many indicated that their governments had not yet had time to agree on the exact size of contribution to make, while others claimed that short-term economic problems made it impossible to make a contribution now.

Several contributions were received from developing countries themselves. These admitted that the size of the payments they were able to make was small compared to the overall target, but emphasized that the contributions were intended primarily as a token of support for the fund. Thus Samoa pledged \$1000, Tanzania pledged 30,000 Tanzanian shillings (equivalent to \$3,614), and Lesotho pledged \$575.

Several of the 'middle income' developing countries agreed to contribute larger amounts. Nigeria, for example, promised

\$250,000, China agreed to contribute \$264,000, and Mexico has indicated that it is likely to make a similar contribution.

Predictably — although with some surprises — the major contributions to the new fund will come from the developed countries. Of the definite commitments made in New York, Italy will contribute over \$9 million in line with its efforts to increase substantially its aid to developing countries, the Netherlands and Sweden will each contribute \$5 million, and Norway, Switzerland and Austria — the host of last year's conference — \$2 million apiece.

Delegates to the pledging conference from both France and Germany indicated that, although administrative reasons had made it impossible so far to earmark specific sums for the new fund, both intended to make contributions of about \$5 million.

Of the other major industrial countries, Britain had made it clear at Vienna that cutbacks in foreign aid made it impossible to commit any new money to development projects (and indeed no British delegation turned up for the pledging conference). Japan said it is still thinking about whether to contribute; and Canada stated that its government had decided to channel all new aid for science and technology in developing countries through the International Development Research Center (IDRC).

The US contribution, initially expected to be considerable, has fallen victim both to general cutbacks in federal expenditure, and to political conflicts that have surrounded Congress's successful torpedoing of the administration-backed Institute for Scientific and Technological Cooperation (ISTC).

In Vienna, US delegates had talked informally of a contribution in the region

of \$50 million. By the Autumn, this had dropped to \$25 million, and when President Carter's budget request to Congress was delivered in January, it had fallen to \$15 million.

Now it looks as if the contribution will be even lower. The US delegation to last week's meeting stated that its contribution would be between \$10 million and \$15 million — and it is thought that the lower of the two is the more likely. In addition, the US attached two conditions to its contribution. Firstly, that it should not be more than 20% of the total fund; and secondly that "significant contributions are made by countries receiving large incomes from oil exports".

Such contributions are expected, but have not yet materialised. Saudi Arabia, announced that it would indeed provide support, but that the precise amount was yet to be decided by its government. And Venezuela, one of the Latin American countries which had been arguing most strongly for new financial mechanisms, surprised many of those present by stating that it, too, while prepared to support the fund, had not yet decided on the extent of its support.

Despite some disappointment that the initial total had not been higher, UNDP said that they were well satisfied with the results of the pledging conference, and are now finalising procedures for deciding how the money should be distributed in a way that supports the final recommendations of the Vienna conference.

In closing the conference, UNDP administrator Bradford Morse said that the contributions received so far meant that the interim fund would be able to operate on 1 May, and several grants are expected to be made soon after that date.

Mr Morse stressed that the contributions promised were only "a first step" towards the target agreed in Vienna, and that a further opportunity for contributions would be provided at a later date.

David Dickson

'Golden Fleece' recipient settles for \$10,000

A MICHIGAN scientist who sued Senator William Proxmire for libel after the senator had awarded a "Golden Fleece" award for the scientist's research on the behaviour of animals under stress has accepted an out-of-court settlement of \$10,000.

The scientist, Dr Ronald Hutchinson, who was previously director of research at the Kalamazoo, Michigan, State Mental Hospital, had received a grant of \$500,000 from the National Aeronautics and Space Administration to support his research. However the grant had been ridiculed by Senator Proxmire as a waste of public funds, stating that the research "should make the taxpayer's as well as (Dr Hutchinson's) monkeys grit their teeth". Last year the Supreme Court ruled that Senator Proxmire could not claim

parliamentary privilege, since the remarks were made not only during congressional debates, but also in press releases and during television appearances.

In making the payment last week, Mr Proxmire issued a statement admitting that some of the statements made about Dr Hutchinson were incorrect. For example, he retracted the claim that Dr Hutchinson's projects were extremely similar and perhaps duplicative, and also that Dr Hutchinson had made a fortune from his research with monkeys. Senator Proxmire and Dr Hutchinson have agreed, following the settlement, that "further litigation is unnecessary". However, an aide to the Senator pointed out that the Senator had not apologised for making the award — and intended to make further "Golden Fleece" awards in future to those whose research projects sounded particularly pointless. □

Sweden

Limited nuclear programme favoured

IN the referendum on nuclear power held on 23 March, 58% of Swedes voted for the completion of the present 12 reactor programme, but only 18.7% gave their approval to anything beyond that.

The referendum was a political exercise from start to finish (see *Nature* 13 March 1980, pages 117-8), and it came as no surprise that the combined forces of the two pro-nuclear options outweighed the support mustered by the single anti-nuclear one. Nevertheless, the success of the anti-nuclear movement should not be underestimated. Against the opposition of three of the four major parties, the trades union movement and industry, it managed — with far less money but far more personal engagement than its rivals — to gather nearly 40% of the voters to its side. The members of the anti-nuclear campaign, led by Lennart Daléus, are unanimous that their fight will go on, although the form of their future organization has yet to be decided.

On the pro-nuclear side, the softer option which recommended carrying out the planned 12-reactor programme but not building any more turned out to be marginally the most popular option of all, polling 39.3%. The more enthusiastically pro-nuclear option polled 18.7%. The fact that nearly 78% of the voters supported options which, with some credibility, demanded phasing out nuclear power, suggests that the population at large accepts nuclear power for a limited period while renewable energy sources are further developed, but by no means wholeheartedly embraces it as the energy system of the future.

Even if this is a reasonable interpretation of the attitude of most people, it remains to be seen whether the politicians will act on it. While they will be under intense pressure to increase funding for renewable energy sources, their immediate tasks will be to bring more reactors on-line. It seems certain that the Ringhals-3 and Forsmark-1 reactors will be quickly loaded: permission to load them has already been given but the actual loading was held up pending the referendum result. The State Power Board has also sought permission to load the Forsmark-2 and Ringhals-4 reactors, but as the reprocessing contract presently in force between the Swedish nuclear fuel supply company (SKBF) and the French firm Cogema does not provide for sufficient capacity to reprocess all the spent fuel from these two reactors, permission to run them will initially be limited to that time which will not produce more waste than the present contract could handle.

If, as the board hopes, Forsmark-2 were loaded in the spring of 1981, and Ringhals-4 in the spring of 1982, the present agreement would take care of

wastes produced from them both until the end of 1985. SKBF is currently trying to persuade Cogema to reprocess an extra 50 tons of spent fuel, which would cover the reactors until the end of 1986. Construction work will also go ahead on the depot for intermediary storage of spent fuel near the Oskarshamn reactors. According to a spokesman at the State Power Board, it seems unlikely that new reprocessing agreements will be concluded in the 1980s, so this depot will have to take care of spent fuel until new reprocessing agreements could be made in the longer term or until a decision were taken to store the waste directly, without reprocessing it.

Anti-nuclear Centre Party Prime Minister Torbjörn Fälldin has no intention of resigning, in spite of the fact that he had

staked all his prestige and moral strength behind the anti-nuclear campaign. His reaction to the result was to say that the people's desire for a maximum of 12 reactors must be respected. This has been seized on by his opponents as an opening shot in a campaign to do away with the twelfth reactor, Oskarshamn-3. The present government is a coalition of the Conservative, Liberal and Centre parties, and such a campaign would be carried on for purely political motives. It would be supported by some sections of the Liberal and Social Democratic parties, but staunchly opposed by the Conservatives' leader, Goesta Bohman, who backed the referendum's most pro-nuclear option. The coalition is undoubtedly in for some tough in-fighting.

Wendy Barnaby

Aldabra has the largest breeding colony of frigate birds (Fregata) in the western Indian Ocean.

Environment

Aldabra faces problems

ALDABRA, the atoll in the Indian Ocean that narrowly escaped becoming an air staging post 13 years ago, once more faces an uncertain future. On 31 March wardenship of the atoll and its ecological treasures passed from the Royal Society, which has maintained a programme of research and conservation since the first alarm, to the Seychelles Islands Foundation. This new public trust has members representing the Seychelles government, the Royal Society, the Smithsonian Institution and international organizations well attuned to the scientific value of an island virtually unscathed by human interference, but its task will not be easy. The foundation will need \$120,000 a year to maintain its research station and scientific programme.

The inhospitability of Aldabra has preserved it from most of the exploitation

suffered by other oceanic islands. The goats, cats, rats and mice introduced after 1880, when a small settlement began on the west island, have not wrought ecological havoc on the other three islands of the atoll. And so when the UK government announced in 1966 its intention to set up a military airfield on the atoll, ecologists realized that they were about to lose a unique ecosystem, where biogeographical and evolutionary theories could be tested.

The Royal Society became the focus for international concern, and mounted an expedition in 1967 to make an inventory of the terrestrial and marine features of the atoll before development began. But in the meantime the plans for the airfield were abandoned, and the society established a more permanent presence. A small research station was built, and in 1971 the society acquired the lease of the atoll, making possible a more comprehensive programme of research, which continued when Aldabra passed into the care of the Republic of Seychelles in 1976.

Since then almost 100 visitors have studied the geology, flora and fauna of Aldabra, making it one of the best known of all oceanic islands and coral atolls. Among the most spectacular of the fauna is the unique colony of about 150,000 giant tortoises, *Aldabrachelys gigantea* (a subspecies of *Geochelone*).

The future of this work is uncertain because the Seychelles Islands Foundation must rely on its own financial resources. In November 1979 it launched an appeal for at least a million dollars to provide an endowment, the income from which could be used to conserve Aldabra in perpetuity. So far more than \$300,000 has been raised, but that will not support the scientific presence much beyond the end of 1980.

Mary Lindley

The World Wildlife Fund, 29 Greville Street, London EC1 8AX, is a focus for the appeal in the UK.

PLANNED changes in Bulgaria's higher education system are designed to provide an annual crop of graduates whose training has been specially tailored to that year's economic needs. Final details of the plan have yet to be worked out, but it appears that at least some of those involved in the new scheme view it with misgivings.

According to Professor Angel Pisarev, Deputy Chairman of the State Committee for Higher Education, the need for the reform has its roots in the pre-war structure of Bulgarian education. At that time the country had no higher technical education whatsoever, and budding engineers had to go to Germany, France or Hungary for their training. Immediately after the war, it was decided to build up a network of polytechnics, giving a degree-equivalent training in such subjects as machine construction, electrotechnics, chemical engineering (including food technology), building and architecture. In all, Bulgaria now has 10 such polytechnics, five of them in Sofia.

Meanwhile, the pure sciences remained the province of the universities, (although a major change in 1972 "integrated" the University of Sofia and the Bulgarian Academy of Sciences, in a scheme by which the Academy took over part of the training of doctoral students, both bodies remaining autonomous).

Measures for implementing the new scheme were approved last year, and an

Eastern Europe

Higher education in Bulgaria

interim system was introduced this academic year to alter the content of lectures and "give more knowledge in the fundamental subjects and a greater practical knowledge at the end", plus an extra 4-5 months of practical education after the academic course but before graduation. The new scheme, to be introduced in 1981, is more radical.

First, the university or polytechnic course, only recently extended from four to five (officially 4½) years, in line with Soviet practice, will be extended to 5½ years. In the first two years, students will receive "fundamental preparation" in fairly generalized courses (physico-mathematical, chemical-biological, electrotechnical, etc.). At the end of that time, they will split up into "general specializations", on the basis of a document drawn up in consultation with factories, agroindustrial complexes and the like. The ministries concerned, having once ordered a certain number of students, will have to find them a job at the end of their

course. There will be no detailed assignment at this stage, since 15-20% of students fail to graduate.

Job assignment will come at the end of the fourth year. Prospective jobs will be posted on notice boards and research posts will be advertised at the same time. During the final year and a half, the student will receive his education partly at the university and partly at his future place of employment. (In the case of a future science teacher, he will do his pedagogics course at this stage.) Finally, after 5½ years the student will graduate and proceed to his appointed job.

According to advocates of the scheme, not only will the new method relieve the student of worries about future employment during their final years; it will also allow the unification of higher education throughout the country. In some years, Pisarev admitted, certain specialisations may be completely closed if no further specialists in those fields are deemed necessary.

Industry, said Pisarev, neither wants to nor can come to terms with the new system — a reaction which may not be unconnected with the fact that industry will have to bear some of the cost of laboratory work in universities and technical training. Bulgaria already has a contract research system involving some students. Now such research will be an obligatory part of the 'basic educational process'. **Vera Rich**

Interferon

Weizmann's interferon entries

THE latest entries for the great interferon race come from an international bevy of owners, headed by the Weizmann Institute in Israel. Not wishing to go nap on a single entry, the Weizmann has simultaneously backed three separate candidates in the hope that at least one will give them a share of the pay-off. Of the three, two involve cell culture techniques and the other embraces genetic engineering.

The genetic engineering project is under the scientific aegis of Professor Michael Revel of the Weizmann Institute and Professor Pierre Tiollais of the Pasteur Institute whose laboratories have considerable experience in interferon and recombinant DNA, respectively. Already their collaboration has resulted in *Escherichia coli* which are producing trace amounts of interferon, an achievement similar to that of molecular biologists in Zurich backed by Biogen (see *Nature*, 24 January 1980, p319) and, before them, Japanese scientists led by Professor Taniguchi at The Yeda Research and Development Company, which handles industrial processes arising out of the Weizmann's research, together with the Pasteur filed an Israeli patent application for the cloning of the human

interferon gene in November 1979.

Yeda is now collaborating with the Cetus Corporation in Berkeley, California in an attempt to improve the bacterial yields of interferon and to scale up the process.

Yeda is also involved in separate attempts to produce fibroblast and lymphoblastoid interferon by cell culture techniques. Professor Revel's team can already do that on a laboratory scale. To scale up production of lymphoblastoid interferon, an arrangement has been made to use the facilities of the Merieux Foundation in Lyons, France. For fibroblast interferon, Yeda and the Swiss Ares Company are building a plant in Israel.

For those who wish to wager a bet, it seems that the Weizmann's recombinant DNA entry is up with the leaders whereas the cell culture candidates are some way behind competitors such as Searle and Wellcome Research Laboratories. There are, however, many dark horses, and undeclared entries to contend with. □

United Kingdom

Science budget steady

A FOUR-year period of relative stability for overall science funding is promised by the

UK Government in its White Paper on Expenditure Plans until 1983-84. But in the division of the 1980-81 science budget the Science Research Council have, on paper at least, received only 52.5% compared with 55% a year ago.

The money available in the 1980-81 science budget will be £383m. It is planned that the budget will be the same in real terms next year and 1% higher in 1982-3 and 1983-4. In announcing this, the White Paper says "The Government attach importance to the support of basic science, in which the United Kingdom excels, as an investment in the country's industrial and intellectual future." Whether or not that sentiment tallies with a four-year static science budget has to be judged in the context of a 9% reduction in expenditure on education planned over the same time.

Of the £383m science budget for 1980-81, the Agricultural Research Council will get £35m, the Medical Research Council £71.8, the Natural Environment Research Council £45m, and the Science Research Council £201.1m with the rest being divided among the Social Science Research Council, the British Museum, Natural History and the Royal Society. Compared to its share of the total a year ago, the Science Research Council appears to have lost out to the Medical Research Council (+1.5%) and the Natural Environment Research Council (+0.7%).

NEWS IN BRIEF

No change for US nuclear export licensing

UNDER heavy pressure from the US Congress, President Carter has backed off proposals to remove responsibility for issuing licenses for the export of nuclear fuels and technology from the Nuclear Regulatory Commission (*Nature*, March 20, page 201).

Several members of the administration, including Mr Gerard Smith, Assistant Secretary of State for non-proliferation matters, had lobbied strongly for the change, arguing that the NRC should not be given foreign policy responsibilities. The move was supported by the nuclear industry, which has recently suffered from a poor export performance. However it was firmly resisted by Congress, which argues that in allocating such responsibilities to the NRC under the Nuclear Non-proliferation Act of 1978, it had sought specifically to remove evaluations of the adequacy of safeguards from direct policy considerations. Following President Carter's rejection of the proposed change, an administration official was quoted as saying that the President did not consider it to be "the right time to raise the issue before Congress".

Photocopying company stops multiple copying

THE Gnomon Corporation, a photocopying corporation with branches in eight eastern university towns, including Cambridge (Massachusetts) and New Haven, signed a legal undertaking last week that it would not make multiple copies of portions of any printed material, even if the material does not carry a copyright notice. The company agreed to make the declaration following charges that had been brought against it by eight leading textbook publishers, and backed up by the Association of American Publishers, that material from their publications was being copied without permission, in violation of the revised copyright law of 1978.

The publishers presented evidence against the Gnomon Corporation which they claimed was typical of a huge volume of illegal copying. Each piece of evidence involved the photocopying of at least an entire chapter or complete journal, and in many cases a third to half of a book.

According to the vice-president of the publishers' association, most of the photocopying was of 20-30 copies for university lecturers. The eight publishers filing the suit included Prentice-Hall, John Wiley and Sons, and Princeton University Press.

Gnomon has also accepted responsibility for photocopying done on coin-operated self-service equipment in its stores. The

president of the Corporation, Mr Adam Carley, has said that parts of the agreement are highly objectionable. He considers that his company's copying practices were legal "but we couldn't afford the legal fees to fight the suit".

New committee on recombinant DNA research

AN interdepartmental committee has been established in the US to study the possible health implications of the industrial applications of recombinant DNA research, prompted by the concern of Dr Eula Bingham, Assistant Secretary of Labour responsible for occupational safety and health.

The committee is a subcommittee of the interagency committee on recombinant DNA research, and will be chaired by Dr Gilbert Omenn, associate director of the Office of Science and Technology Policy. The executive secretary will be Dr Bernard Talbot of the National Institutes of Health.

The new committee, which is holding its first meeting next week to decide on a plan of work, has been set three tasks by the interagency committee. First to review the industrial applications of recombinant DNA research. Secondly to assess the need for providing educational information to workers about the techniques they will be coming in contact with. And thirdly to determine criteria for examining the question of potential hazards.

Five-year anti-nuclear campaign launched in UK

FRIENDS of the Earth has launched a £1 million, five-year campaign against the Conservative Government's plan to introduce pressurized water reactors into the UK at the rate of one each year starting in 1982. The campaign aims to turn nuclear power into a major issue of the 1984 general election. It plans to do this through a five-year strategy consisting of increasing public awareness through demonstrations, local elections, and summer schools on nuclear power in the first year; continuing education and initial fund-raising in the second and third years and community organizing and mobilization in the fourth year. The election campaign in the fifth year will support candidates who declare themselves to be against nuclear power.

According to Czech Conroy, FOE campaign director, the programme will emphasize three policy issues — safety, the record of the nuclear industry, and the cost of nuclear power — and three political issues — governmental secrecy on nuclear power issues, the use of taxpayers' funds for pro-nuclear campaigns and the morality of risking nuclear power development without adequate safety and waste disposal facilities.

Research reactor for Bangladesh

THE Bangladesh Atomic Energy Commission recently signed a contract with the US company General Atomic for the supply of a 3-MW TRIGA Mark-II pulsed research reactor. The TRIGA (Training Research and Isotope Production Reactor by General Atomic) is a water cooled, graphite reflected reactor suitable for research training and isotope production. It has a steady state power level of 3 MW and a peak power output of 1,200 MW. The reactor will be installed at the Bangladesh Atomic Energy Commission's research establishment at Savar, about 50 kilometres north of Dacca.

Givaudan negotiates out-of-court over Séveso

THE Givaudan Company, a subsidiary of Hoffman-La Roche, is negotiating with the Italian government and regional authorities for payment for damages caused by the uncontrolled release of dioxin from its ICMESA chemical plant in Séveso on 10 July 1976. If the Commission of Parliament for Lombardy approves the settlement, Givaudan will pay £24.3 million to the Italian state and the Lombardy regional authority for their expenses incurred in public health, social assistance, damage to the environment, and loss of local industry and trade. Givaudan will also complete at its own expense the decontamination work currently underway.

AUT fights London layoffs

In a letter to Lord Annan, the Vice-Chancellor of the University of London, the Association of University Teachers criticizes the Flowers report on the reorganization of medical education in London (*Nature*, 6 March, page 5) for its potential to make teaching and research staff "the victims of proposals to cure the alleged defects of a system for whose construction they bear no responsibility".

According to John Akker of the AUT, the Flowers report does not say how its proposal to save £3 million from "rationalization" of staff (out of a university budget of £200 million) should be put into effect. The AUT also criticizes the report for not first estimating whether or not savings could be made from sales of buildings and saved maintenance costs and also for not including the cost of redundancy payments and rehousing of staff in expanded facilities at non-threatened institutions.

East-West fencing at Geneva

The outcome of the recent review of biological weapons control does not bode well for other arms control negotiations, writes **Julian Perry Robinson**

THE 1972 Biological and Toxin Weapons Convention (BWC) represents the only real disarmament measure agreed since the World War II peace treaties because it is the only one that has required the destruction of existing stocks of weapons. But, as a model for further agreements, it is weakened by flimsy arrangements for verification. These were the subject of fierce controversy at a conference to review the convention, held in Geneva at the end of last month.

At the one extreme was the Swedish delegation seeking amendment of the treaty to provide for an expert consultative committee under the UN Secretary-General, empowered to investigate complaints of violation. At the other extreme was the Soviet delegation, arguing that since no one had yet raised a complaint under the procedures which the treaty already provided, there was no need to elaborate additional procedures. Between the two was the UK.

Two thirds of the way through the conference, however, there was a turn of events which paradoxically strengthened the position of the USSR. The US State Department suddenly used one of its daily press briefings in Washington to declare itself suspicious of Soviet compliance with the BWC, citing an unexplained outbreak of infectious disease in Sverdlovsk eleven months previously. In various different forms since October, this outbreak has been reported in the British and West German press, with speculation that an accident had occurred in a clandestine biological weapons facility (*Nature*, 27 March, page 294).

The abruptness of the US announcement, and its failure to display any very solid substantiation, strongly suggested that the Americans had launched a wrecking operation, driven by growing anti-arms control sentiments in Washington, and perhaps by the pro-chemical weapons lobby. The drafting party which was then putting together the bones of the final declaration of the conference felt compelled to avoid language which suggested that the BWC had been fully observed, but the US delegation eventually let it be known that it would not raise the matter at the conference until the final plenary session. Since the text of the final declaration should by then have been adopted, this implied that the US delegation was, after all, going to maintain its initial stance of preserving the BWC against damaging aspersion.

The Sverdlovsk allegation very much affected the content of the final declaration

on the thorny issue of the consultative committee. On the one hand it illustrated most graphically the need for some form of international verification procedure. On the other, it suggested that the USSR would be the subject of the first complaint to be brought before the committee, and few states were happy to contemplate the political furor that would ensue, and the attendant threat to the BWC's continuation. The outcome was ambiguous talk about the possibility of a "consultative meeting . . . at expert level" being convened under the verification article of the treaty, without details about who would convene it or what it was supposed to do. Its only merit is that it leaves the question open for further consideration "at an appropriate time". The Soviet delegation had argued that a review conference was not a proper place for amending a treaty — a principle which many delegations subscribed to, including those worried about verification (presumably because of fear of setting a precedent for the 1968 Non-Proliferation Treaty review in August this year).

Some delegations appeared to have taken note of a submission made by the Pugwash movement, which in one of its East-West conferences of senior scientists back in 1959 had set the ball rolling towards international agreement on the BWC. Part of its submission was that highly toxic substances of military potential might well become accessible via certain of the new biotechnologies that are beginning to attract heavy investment, and that if this were to happen it would not be clear whether the substances would be treated as toxins within the meaning of the BWC.

The three co-depositaries of the convention — the US, the USSR and the UK — were reluctant to concede that there might ever be any problems over the scope of the treaty, for this might undermine confidence in it; and they produced an anodyne joint paper on scientific developments since 1972, including DNA hybridization techniques, which concluded that nothing had happened which necessitated any clarification of scope. The conference did not take serious issue with this conclusion. But it decided, largely on the insistence of Sweden, to hold a further review conference sometime between 1985 and 1990.

There are certainly several loose ends hanging out of the BWC which might cause problems as long as there is no analogous convention on chemical weapons to tie them up. This is recognised in Article IX of the BWC, which requires party states to

"continue negotiations in good faith" on chemical weapons. When the operation of this article came under review, many of the delegations strongly criticised the two superpowers for the apparent absence of major progress in their secret bilateral negotiations on the subject (the eleventh round of which was then in session down the street), and for their opposition to the opening of complementary negotiations within the multilateral UN Committee on Disarmament (the CD). Chemical weapons reached the CD agenda soon after the BWC review conference had begun, which seems to have hastened a compromise on the complementary negotiations issue. But apart from the Americans, no one seems at all happy with the compromise, which calls for the convening of an *ad hoc* working group of the CD to "define, through substantive examination, issues to be dealt with in the negotiation on a chemical weapons convention". The primacy of the bilateral negotiations is thus preserved for the foreseeable future, so that the prospects for worldwide prohibition of chemical weapons will remain dependent on the caprices of the superpowers.

The BWC review showed very clearly that the superpowers are in no mood to accommodate one another on chemical or any other arms-control matter, despite growing international tension. The Americans seem set on a policy of brinkmanship threatening (as with the current calls from Washington for an expansion of NATO chemical-warfare capabilities (see page 286)), to destroy the basis of negotiation. Soviet reactions (like their refusal to accept the modest degree of international verification inherent in the BWC consultative committee proposals) are commonly seen in the West as intransigence on basic issues. Neither has the USSR displayed any understanding of the roots of western mistrust. It did not respond to the suggestion that states should voluntarily declare whether or not they had formerly possessed biological weapons.

Many of the participants to the conference regarded the affair as a dry run for the second NPT review conference in August. This attitude no doubt stemmed from the fact that biological weapons make little sense militarily and have never been developed to their full mass-destructive potential. But the chief significance of the meeting lay rather in the influence it might have on other arms control negotiations.

In private conversation about the Sverdlovsk allegation, a Soviet representative doubted whether there could now be any progress in the CD on chemical weapons or anything else at all important this year. Perhaps he was speaking in the heat of the moment — but the present climate does not favour optimism. □

CORRESPONDENCE

Chinese Scientific American

SIR, — In the second of his three recent articles on the development of science and technology in China (*Nature* 7 February, page 516) Tong B. Tang makes the statement, based on his visit to China at the end of last year, that "There are no cover-to-cover translations into Chinese" of foreign scientific journals. It may interest your readers to know that this statement was not true then and is not now. *Ke Xue*, the Chinese-language edition of *Scientific American*, began regular publication in China with its January 1979 issue, lagging the parent English-language edition by 14 months. Beginning with the January 1980 issue *Ke Xue* will lag the parent edition by only four months. The paid monthly circulation of this "cover-to-cover translation into Chinese" of a foreign scientific journal is currently 25,000.

GERARD PIEL

Scientific American, New York, US

How safe are safety cabinets?

SIR, — There has been much concern about the performance and testing of microbiological safety cabinets built before the publication of the new British Standard (BS 5726) (*Nature*, 278, 29 March, 1979, p.384). This concern is now being extended to cabinets built after the introduction of the standard and claiming conformity with it. Many of the problems are centred on the Class II Safety Cabinet which is designed to provide protection both to the work and the worker. In terms of safety, the two most important features of such cabinets are:

- that pathogenic aerosols are adequately contained by the inflowing air-streams; and
- the reliability of the filtration system is assured.

The BS allows that once the performance of a prototype cabinet has been validated, the subsequent production versions may be assumed to have satisfactory performance, provided that they have the same physical dimensions and that the air-flows do not differ by more than $\pm 10\%$ from those of the prototype. We do not believe that this principle is in practice adequate to provide safe working conditions, particularly in open-fronted Class II cabinets.

We have undertaken trials to evaluate production versions of a number of these cabinets and to correlate different methods of determining operator protection factors. Early in these trials the disturbing fact emerged that several cabinets reputedly identical in design to prototype models which had performed satisfactorily, failed to provide the required operator protection. The monitoring instruments of the cabinets indicated safe working conditions, and it was only from the results of aerosol containment tests that faults were revealed.

Most of the defects like faults in fan motors and their controls, or defective filter seals could have been rectified on site. But, more important, we have found that relatively low air movements in laboratories can severely affect containment; the approved design may not be adequate in such circumstances.

We urge most strongly that commissioning of new cabinets should include tests for containment, filter integrity and the quality of their seals; without these on-site tests there can be no guarantee that the cabinet will perform within specification.

Section six of the Health and Safety at

Work Act places an onus on suppliers, manufacturers and installers to provide cabinets suitable for the use for which they were designed and complying with the requirements of BS 5726. The customer should satisfy himself that these obligations have been met. Such tests must be included in the purchase price and not left as options for intending purchasers.

The DHHS operates an effective evaluation scheme for Class I cabinets, and there is clearly a need for a similar service for Class II types. This should cover all the requirements of the British Standard, but should in our view be supplemented by a test following installation on site. Agencies operating a rigorous approval scheme should be accredited by the British Standards Institution.

The results of the recent trials will be reported in detail in due course. One finding can be mentioned now: namely, that when tests using micro-organisms are unacceptable an alternative method making use of an aerosol of potassium iodide may be a suitable substitute.

Synergism v. cost benefit

SIR, — In a disturbingly high proportion of experiments on mixtures for pest and disease control, decisions are based on questionable criteria. Many biologists appear to have become convinced that the ultimate goal is synergism. In screening candidate mixtures for further study a mixture that is not considered synergistic is sometimes abandoned.

Certainly, it is desirable to gain understanding of the mechanism of joint action, but often the need is only to assess the net observable effect of applying one mixture or another. The purpose is usually to minimize an overall cost, where the cost or loss function may include not only the cost of materials, equipment and labour, but also the losses in terms of environmental and health hazards, and damage to non-target organisms. On this basis, even mixtures with some degree of antagonism may sometimes be worth considering.

The point at issue is illustrated in Fig. 1, which shows contours of equal effect (isoboles) and of constant cost, plotted against rates of application of the components of a two-component mixture, assuming each component to be individually active. If the cost is linearly related to the amount of each component (Fig. 1a), a mixture can have no advantage over a single material unless the isobole at the required level of response is

sufficiently concave upward. The requirements for upward concavity are more severe if the cost curve is also concave upward (Fig. 1b), but if the cost curve is concave downward (Fig. 1c) even a mixture with a concave-downward isobole might be of practical value. Cost curves such as these can arise, for example, if either component has adverse effects on non-target organisms or on the environment, often the very reason for investigating a mixture.

All this may seem to be so obvious as to need no stating, but mathematically-inclined scientists might be surprised to discover the extent of the primary emphasis on synergism, and the relatively slight or belated consideration of cost-benefits.

Even if demonstration of synergism is considered relevant, there are varied concepts of what constitutes synergism, except in the case where only one component of a mixture is active on its own. I have elsewhere reviewed some of the confusion that exists in one field of application, a confusion that has its roots in failure to realise the importance of defining an appropriate reference model to represent absence of synergism (and antagonism). For example, many weed scientists, using a method due to Colby, consider that any mixture is synergistic if the proportion surviving is less than the product of the proportions that survive the separate components. On this basis, a "mixture" of two aliquots of the same material would be judged synergistic.

Other biologists consider a mixture to be synergistic only if its isobole is concave-up. The models corresponding to absence of synergism by these two definitions are, in general, quite different. Either of them, or neither, may be biologically relevant. Occasionally both definitions are even treated as if synonymous. Another common misconception is exemplified by the "definition" in the *Herbicide Handbook*. "Complementary action of different chemicals such that the total effect is greater than the sum of the independent effects". On this basis, a mixture for which the percentage responses to the separate components sum to more than 100 would always be classified as antagonistic.

The problems of definition are neither easy to resolve nor to explain and demonstration of synergism in a fundamental sense may require specialized biochemical experimentation.

The aim of this communication is to plead for recognition of the real purpose of any study of joint action, and for appropriate assessment of the results. Cost curves may be difficult to establish in absolute terms, but even a rough idea of their forms could usefully influence the focus of screening and field trials of mixtures.

PAMELA M. MORSE

Statistical Research Section, Engineering and
Statistical Research Institute, Agriculture
Canada, Heritage House 54, Central
Experimental Farm, Ottawa, Ontario.

Fig. 1 Curves of constant response (broken lines) and curves of constant cost (solid lines) for mixtures of two materials S_1 and S_2 at doses Z_1 and Z_2 respectively. The cost attributable to S_2 has been assumed to be proportional to Z_2 , so that in each diagram any two cost curves are at a constant vertical distance apart. Examples in which a mixture would be economically advantageous have isoboles shown by dashes (---); mixtures with dotted isoboles (....) could not cost less than S_2 applied alone.

NEWS AND VIEWS

Archaean stromatolites and the search for the earliest life

from Euan G. Nisbet

SEARCHING for the oldest traces of life on Earth is a difficult business — if the evidence for the existence of life is good, the rocks are usually not very old; if the rocks are very old the evidence for life is usually not convincing. In this issue of *Nature* Lowe (page 441) and Walter *et al.* (page 443) separately report two probable examples from the Pilbara, Western Australia, of $3.4\text{--}3.5 \times 10^9$ yr old stromatolites (sedimentary structures formed by algae or possibly other organisms). These may be the oldest macro-‘fossils’ yet found. These two reports and other recent work suggest that life began very early indeed in the Earth’s history.

To be convincing, a report of evidence for life in the Archaean (that period before 2.5×10^9 yr ago) must demonstrate both that the structures described are unambiguously biogenic and that the geochronological control is accurate. Cloud and Morrison (*Precamb. Res.* 9, 81; 1979) distinguished three categories of evidence, discriminating between ‘permissive’, ‘presumptive’ and ‘compelling’ evidence for life. ‘Possible’, ‘probable’ and ‘definite’ (as far as any geological evidence is definite) would be another way of putting it. Very little of the evidence for life in the Archaean is ‘compelling’, but there is a considerable body of evidence in the ‘presumptive’ class. Careful geochronological work, in particular by O’Nions, Hamilton and coworkers, by Pidgeon and by Moorbath in various very old terrains is promoting the search for better and older evidence.

Palaeontology in the Archaean takes three main forms: the study of possible microfossils; the analysis of rocks for chemical traces of life; and the study of stromatolites. The identification of Archaean microfossils is often not wholly convincing (Muir *Publs. Geol. Dept., Univ. Western Australia*, 2, 11; 1978). Microstructures which could be fossils have been reported from the Barberton area (3.5×10^9 yr) by Knoll and Barghoorn (*Science* 198, 396; 1977) and from the Pilbara by Dunlop *et al.* (*Nature* 274; 676; 1978), but in their review Cloud and Morrison concluded that the oldest structurally preserved microfossils for which there was conclusive evidence were 2.3×10^9 yr old (post-Archaean). The older examples from Barberton and the Pilbara are ‘possibles’, but the evidence is not conclusive. The second line of research, chemical analysis, includes both stable isotope work and the study of organic compounds in kerogen extracted from Archaean sedimentary rocks. Schidlowski *et al.* (*Geochim. cosmochim. Acta* 43; 189; 1979) studied carbon isotopes in 3.7×10^9 yr old Isua metasediments, from West Greenland. Their evidence suggested that the terrestrial carbon cycle was virtually stabilized at least as early as 3.7×10^9 yr ago — the oldest ‘possible’ evidence for life on Earth. Sklarew and Nagy (*Proc. natn. Acad. Sci. U.S.A.* 76; 10; 1979) have isolated possible remnants of biologically made carbohydrates from the Belingwe stromatolites, Zimbabwe Rhodesia (2.7×10^9 yr old). However, post-depositional contamination is a major problem in this research, especially when early Archaean samples are studied.

Archaean stromatolites are on a much larger scale — they can be ‘hit with a

hammer’, but in some cases it is difficult to distinguish between stromatolites and similar but abiogenic sedimentary structures. At best stromatolites offer ‘compelling’ evidence for the existence of life, since analogous modern structures are well-known and have been studied in detail (particularly at Shark Bay, Western Australia). Thus the evidence reported by Lowe and Walter *et al.* is of especial importance. At present the oldest compelling evidence for life on Earth comes from stromatolites about 2.7×10^9 yr old, especially from the Slave Province, Canada (Henderson *Can. J. Earth Sci.* 12, 1619; 1975), from Steep Rock Lake, Canada (Jolliffe *Econ. Geol.* 50, 373; 1955) and from the spectacular outcrops near Belingwe, (Bickle *et al. Earth planet. Sci. Lett.* 27; 155; 1975, Martin *et al. Precamb. Res.* in the press). Slightly older, and not so well exposed, are the probable stromatolites (Mason & von Brunn *Nature*, 266, 47; 1977) of the Pongola Supergroup, S. Africa ($2.9\text{--}3.0 \times 10^9$ yr old). Stromatolite-like structures also occur in the Barberton area, S. Africa, but they may be of inorganic origin. Thus these two new reports of 3.5×10^9 yr old stromatolites add very significantly to the evidence for the existence of life in the early Archaean.

Lowe describes internally laminated conical mounds, interpreted as stromatolites, in recrystallized evaporites which form part of the Warrawoona Group. Criteria for biogenicity cited by Lowe include morphological similarity with younger stromatolites and similarity of sedimentary environment with later examples. Lowe considers that forms similar to *Conophyton* occur in the Pilbara; if so, this very considerably extends the supposed age range of this type

of stromatolite since the only other Archaean example of *Conophyton* is at Belingwe (Martin *et al. Precamb. Res.* in the press). Walter *et al.* report a single nodular structure, also from the Warrawoona Group. They consider that this structure could not have formed abiogenically and thus identify it as a stromatolite.

How will these two reports be regarded by properly sceptical geologists? 'Probable' is the most likely response. The burden of proof is very great in material as old as this, but it is interesting that 'possible' microfossils of the same age have been reported from the same area by Dunlop *et al.* Further fieldwork may produce more definite evidence. Thus the oldest 'possible' evidence for life is that

from Isua (3.7×10^9 yr old); the oldest 'probable' evidence is from the Pilbara stromatolites reported in this issue of *Nature*; and the oldest 'compelling' evidence from the superb late Archaean stromatolites in Canada and near Belingwe. Nevertheless, the 'probable' evidence from the Pilbara, together with the possibility that the Isua rocks do record biological activity, suggest that life on Earth began very early indeed in the geological record. It is difficult to imagine that the surface of the Earth was hospitable to life before, say, $4.2-4.3 \times 10^9$ yr ago. Thus, if life did originate on Earth, the processes leading up to it (*Proverbs* 8.27) must have happened very quickly indeed. A few hundred million years is not long on a geological time scale. □

oncogenes but promoters or other DNA sequences which, by virtue of their integration, induced expression of transforming genes in the recipient NIH 3T3, a cell line and therefore not strictly a normal cell. A more surprising feature of this work is finding that the DNA from all chemically transformed and normal cells tested transforms recipients with equal efficiency, suggesting that the chemically-induced oncogene expression is transmitted poorly to recipients. The author's explanation is that the chemicals may have mutagenically inactivated a *trans*-acting repressor of a transforming gene; the oncogene will therefore never be expressed in a recipient in which this repressor is functional and the transformation is thus phenotypically recessive.

Somewhat different results have been obtained by R.A. Weinberg's group (Shih *et al. Proc. natn. Acad. Sci. U.S.A.* 76, 5714; 1979) who transfected DNA from 15 chemically transformed cells to test the hypothesis that transformation was due to the mutagenic action of the chemicals. Although these workers apparently used high molecular weight DNA, they found that DNA from 5 of the clones transformed with high efficiency, equivalent to that observed by Cooper *et al.* only with DNA from transformed recipient cells (not surprisingly, secondary transfections by Shih *et al.* with DNA from transformed recipients did not further enhance transformation). DNA from the other transformed clones and controls showed no significant transformation, in line with the observations of Cooper's group.

It is difficult to compare the findings of these two groups, given the different premises with which they prefaced their studies and differences in materials and technique. Indeed, only one cell line, the methylcholanthrene-transformed BALB 3T3 mouse cell MC5-5, was common to both studies and this, in Cooper's hands, yielded poorly transforming DNA whereas for Shih *et al.* it was an efficient transformer. However, it does seem likely that Cooper *et al.* were studying cells similar to those which Weinberg's group regarded as irreproducible inducers of transformation (Shih *et al.* apparently never used low molecular weight DNA for transfection). Moreover, Shih *et al.* provide clear evidence for cell transformation resulting from a dominant mutation. Whether these mutations can be in either or both structural or regulatory regions remains to be determined and these findings must be reconciled with the evidence of Cooper *et al.* that genes from normal cells can also induce transformation. As both groups realise, elucidation of these interesting questions requires the application of molecular cloning techniques to provide large quantities of transforming cell DNA and Weinberg *et al.* (12th Miami Winter Symposium, 1980, in the press) have

Fishing for oncogenes

from John Wyke

SOME 10 years ago the existence of particular genes which might be responsible for inducing cell neoplasia was first suggested. This 'oncogene hypothesis' proposed that the RNA tumour viruses owed their ability to transform cells to transforming genes (oncogenes) which they may have picked up at some time, perhaps from the host cell itself. In the past decade a wealth of evidence has partially validated this idea, for we now know that the transforming genes of many retroviruses contain sequences that are homologous to regions in the genome of normal cells, the virus presumably having acquired this genetic material by recombination between its genome and the host cell. These cellular homologues of viral oncogenes may themselves be oncogenic if expressed at inappropriately high levels (as may occur when their expression is controlled by a retroviral promoter) and neoplasia may simply be a matter of gene dosage. On the other hand they may become oncogenes only after mutation by physical or chemical means or during or after recombination with a retrovirus (there may or may not be an additional requirement for inappropriate expression). These putative cellular oncogenes clearly have a potential importance beyond the interests of tumour virology. We would like to know their function, how they are regulated and whether their expression is important in cancer induced by agents other than viruses, and for these reasons they are attracting increasing attention.

Two strategies for identifying and isolating cellular transforming genes have recently been reported. One uses the technique of DNA transfection in which

naked DNA from a donor cell is introduced into a recipient, inducing a phenotypic alteration (in the case of putative oncogenes the phenotype sought is morphological transformation). Two groups, both with experience in transfecting retroviral DNA, have applied donor DNA from normal and chemically transformed cells to recipient untransformed NIH 3T3 mouse cells. G.M. Cooper and colleagues (this issue of *Nature* page 422) reasoned that normal cells might contain unexpressed transforming genes which, if they integrate adjacent to an active promoter in a recipient cell, could be expressed. They found that high molecular weight DNA ($> 20 \times 10^6$) from both normal and chemically transformed avian and murine cells did not increase transformation of recipient cells above background levels but that fragmented DNA from the same donors, sonicated to molecular weights of $0.3-3 \times 10^6$, transformed recipients at a low level (0.003 transformants per μg DNA). They suggested that fragmentation may have separated potential transforming genes from linked cell regulators and these liberated oncogenes, in a few instances, integrate next to an active promoter in the recipient. This interpretation was supported by using DNA from the transformed recipient as a donor in further transfections, when it was found that the high molecular weight DNA was now a very efficient transformer (0.1-1.0 transformants per μg DNA). This indicated to Cooper *et al.* that the oncogene and its newly-acquired active promoter were now transfected in tandem.

These results provide *prima facie* evidence that normal cells contain potential transforming genes, but one slight caveat is the possibility that DNA from the original donors contained not

John Wyke is at the Imperial Cancer Research Fund Laboratories, Lincoln's Inn Fields, London.

already embarked on this project.

The other strategy for picking up oncogenes uses the penchant of retroviruses themselves for acquiring cell sequences. Essentially, the idea is to passage a non-transforming virus through a cell which is transformed, and thus expressing cell oncogenes, reasoning that recombination between virus and oncogene can occur, giving rise to a transforming virus. This ploy should permit not only stable acquisition of the oncogene but also its efficient transmission in an expressed form, using the virus as vector, readily enabling studies on the oncogene product and its phenotypic consequences. Naturally, a number of groups over the past 10 years have tried to

capture oncogenes in this way, but with limited success. However, Rapp and Todaro (*Proc. natn. Acad. Sci. U.S.A.* 77, 624; 1980) now claim to have developed a method for generating *in vitro* new mouse retroviruses capable of inducing leukaemias, sarcomas or carcinomas. Although they have not yet purified and characterised their new isolates, their protocol looks promising.

These two experimental approaches together provide a rational way to identify and amplify cellular transforming genes and initial results are encouraging. Soon they may enable us to learn a great deal about the variety, structure and regulation of oncogenes, and how their products effect the cell phenotype. □

fragments of virus DNA containing the TK gene. At first it was assumed that the required gene would have to be chemically linked to the TK gene but more recently it has emerged that the small number of 'competent' cells that accept the TK gene will at the same time accept other DNA fragments present in the culture medium (Wigler *et al. Cell*, 16, 777; 1979). Correct transcription and processing of rabbit globin genomic DNA linked to a cloned herpes TK gene and introduced into mouse cells, has been shown (Mantei *et al. Nature* 281; 40; 1979).

But there is a prejudice about using viruses, even small cloned fragments such as the herpes TK gene as vectors or as selective markers for introducing genes into cells which are destined to be reintroduced into man.

A different approach has been taken by Cline *et al.* (this issue *op. cit.*) who have transformed normal bone marrow cells with cellular DNA and have chosen a system in which the selection of the transformed cells takes place *in vivo*, after the treated cells have been introduced into a new host. As a marker of transformation they used the dihydrofolate reductase (DHFR) gene, which if present in a large number of copies per cell confers resistance to the anti-cancer drug methotrexate, which acts by inhibiting DHFR. Selection *in vivo* is by subsequent treatment with methotrexate. This selective system allows them to use normal bone marrow cells as the recipients rather than a mutant cell line.

A few years ago R. Schimke and colleagues at the University of California, Los Angeles found that resistance to methotrexate is sometimes a result of an unusual amplification of the genes for DHFR, with consequent overproduction of the enzyme which overcomes the inhibition. As their source of amplified DHFR genes, Cline *et al.* took total DNA from a line of mouse cells in which the DHFR genes had been amplified some 30 times.

They used this to transform normal mouse bone marrow cells by a conventional calcium precipitation technique. The treated cells were injected into mice of a different but compatible strain which had been irradiated to clear the marrow of host bone marrow cells. The treated cells could be distinguished from those of the host by their distinctive chromosome pattern. Along with the treated cells were injected an equal number of 'mock' transformed host-type bone marrow cells treated with DNA from non-resistant cells.

The mice were then treated with methotrexate so that injected cells which had received large numbers of DHFR genes and were able to express them would be selected over normal host or donor cells, and, if stem cells, would multiply preferentially. If there is no selection for the added gene, both types of cell will remain in equal numbers, as the only

Reintroduction of genetically transformed bone marrow cells into mice

from Bob Williamson

MANY human hereditary diseases are caused by the malfunction of a single gene coding for a protein, of which the human haemoglobinopathies are the best characterised. Methods based on recombinant DNA techniques now allow fetuses with these disorders to be identified more reliably and easily. Antenatal diagnosis with the possibility of offering abortion is now a reality for several of the haemoglobinopathies. Another (or complementary) approach to the problem of these genetically simple diseases would be gene replacement, in which a normal copy of the deficient or abnormal gene is introduced into the affected tissue after birth. So far this approach remains firmly in the realms of speculation but recent developments in the introduction of genes into mammalian cells are bringing it nearer. The most recent report from M.J. Cline *et al.* at the University of California, Los Angeles (this issue of *Nature*, page 422) concerns the reconstitution of bone marrow in mice with normal bone marrow cells into which a drug-resistance gene has been introduced *in vitro* and the demonstration that cells which are expressing that gene can be selected by treatment *in vivo*.

The initial problems to be faced in developing methods of gene replacement are first, to introduce the required gene into the appropriate cell *in vitro* and to build into the process some way of easily recognising and selecting transformed cells in which the gene is functional. Second, an

effective population of treated cells has to be reintroduced and maintained.

Attempts to transform mammalian cells with fragments of DNA (transformation here means the introduction of DNA into a cell with a consequent change in its phenotype and does not refer to neoplastic transformation) come up against several difficulties. Mammalian cells will accept 'foreign' DNA although normally at very low frequency and there is some evidence that it may be integrated into their chromosomes. The low frequency of transformation is partly because techniques for introducing DNA into cells in culture are rudimentary, but also because only a small proportion of cells in a population appears 'competent' to accept DNA from solution. It is also difficult to find appropriate mutants of mammalian cells which allow selection for newly-introduced gene function.

One way of introducing DNA into mammalian cells, which provides both a selective marker and a higher rate of introduction, is to use modified versions of certain DNA viruses such as SV40 and polyoma as vectors. If the inserted gene is in the correct orientation and near to a functional viral promoter RNA is made from the inserted gene as well as from the virus and genes inserted into these vectors can be properly transcribed, processed and translated (see for example Mulligan *et al. Nature* 277, 108; 1979; Hamer & Leder *Nature* 281, 35; 1979 using β -globin DNA).

Another approach, taking the herpes virus as the starting material is to use the virus thymidine kinase (TK) gene as the selective marker for transformation of TK-deficient cell lines by genes linked to

Bob Williamson is Professor in the Department of Biochemistry, St. Mary's Hospital Medical School, London.

difference in their lineage is the treatment of one with DNA containing large rather than small numbers of DHFR genes.

It turned out that after 30 days, the proportion of marrow cells derived from the DHFR-gene treated marrow culture was greater than 70% in most cases. The proportion continues high as long as methotrexate is administered, but when it is withdrawn the ratio returns to normal. Since the increase was also found in stem cells, this result is puzzling unless one assumes that the DHFR genes are gradually eliminated from the cell population when selection is removed. It is not yet known whether the DHFR genes have become integrated into the cellular DNA; if they are persisting in an episomal state they may be more easily lost. The mice were apparently healthy, as the levels of methotrexate used for selection were not very high. Direct analysis of the marrow cells showed a high level of the enzyme, as would be expected.

One cogent objection that could be raised to this work is that as genes for DHFR do exist in normal marrow cells, it is possible that the resistant cells could have arisen in the treated cells by the amplification of these DHFR genes rather than by the introduction of genes *in vitro*. Indirect supporting evidence that their procedure does lead to transformation and selection of transformed bone marrow cells is provided by other experiments by the same authors (submitted for publication elsewhere) in which cloned herpes TK gene sequences were inserted into mouse marrow cell cultures and these cells were transplanted into irradiated mice of a different chromosome pattern, but otherwise genetically compatible. Unlike the mouse DHFR genes, these herpes TK genes can be unambiguously recognised by their DNA restriction pattern as they are from a human virus and do not normally occur in mouse cell nuclear DNA.

The transplanted marrow did indeed contain herpes TK genes, and these appeared to be integrated in some fashion into the host cell DNA. Moreover, if the mice are treated with methotrexate (which also can select for thymidine kinase by another mechanism) the cells containing the gene are selected for in the marrow.

Bone marrow is at present the only tissue in which one might seriously consider clinical gene replacement in the near future, to correct some of the haemoglobinopathies, for example sickle-cell anaemia. Bone marrow can be relatively easily extracted, manipulated *in vitro* and replaced.

However we do not yet have the answer to the crucial question of whether it will be possible to restore correct control over the introduced genes, for it is absolutely essential that they should be expressed under the same controls as those in normal animals. Expression in inappropriate tissue or abnormal control in the cell in which they are normally expressed could be disastrous. A surplus of one globin chain

would be as harmful physiologically as a deficit, substituting an iatrogenic illness for a genetic one. Before gene therapy becomes a real possibility either ways must be found to insert the required gene into the 'correct' place on the chromosome or other methods

must be found to ensure balanced gene expression.

The final question is, why bother, particularly as antenatal diagnosis is now possible for sickle cell disease and thalassaemia? But there are still many people suffering from these diseases, and there will always be some new ones arising — this in itself justifies the approach. However, the main reason is perhaps that the haemoglobinopathies are quite unusual amongst genetic disease in that carriers can be identified easily. There are many conditions where carriers cannot be detected antenatally, and in this case treatment rather than prevention may be the only feasible strategy. □

100 years ago

The *Photographic News* is responsible for the following:— Everybody knows how jealously the gates of the Royal Observatory are guarded, and what difficulties even scientific men have to gain admission. But Mr. Glaisher, the worthy President of the Photographic Society, and who was until lately Superintendent of the Meteorological Department, tells a story that goes far to prove that nothing is impossible to a resolute man. A vast star shower had been anticipated and its coming heralded in every newspaper. The staff at Greenwich, with the Astronomer-Royal at their head, remained the whole night through making observations and counting the bright meteors as they fell. The weary night passed, and the small hours of the morning came, only to find the jaded observers still pursuing their duty. "That makes 10,704," said our friend Mr. Glaisher. "Beg pardon; how many?" exclaimed a voice behind him. "10,704," repeated the President of the Photographic Society; and then, not recognising the voice, he turned and saw a stranger: "Who are you, and where do you come from?" At first, the only possible conjecture was that the stranger had fallen from the clouds along with the star shower; but it was not so, for, closing a little note-book, he simply replied, "I am the special correspondent of the *New York Herald*. Thank you very much. Good morning." How that special managed to get through the park gates and elude the vigilance of the keepers; how he got inside the walls of the Observatory; how he pressed into the sanctum of the Astronomer-Royal is a mystery to this day; but within a few hours of his interview with Mr. Glaisher the readers of the *New York Herald* printed a correct account of the marvellous star shower, together with many interesting details of the Observatory itself.

The French Exploring Expedition for the Trans-Saharan Railway has left Wargla for the interior of Africa.

Winds in the polar thermosphere

from Henry Rishbeth

THE observations of Smith and Sweeney, reported in this issue of *Nature*, page 437 make a new contribution to knowledge of the polar upper atmosphere — specifically the thermosphere, at heights of 200–300 km. Working in Spitzbergen, during continuous winter darkness, Smith and Sweeney used a Fabry-Perot interferometer to measure doppler shifts of the red 630 nm auroral emission. The instrument points sequentially in different directions and, with a few minutes' integration, typically measures the wind component in the line of sight to within about $\pm 20 \text{ m s}^{-1}$.

The 630 nm ($^3\text{P} - ^1\text{D}$) emission is radiated by the metastable ^1D state of atomic oxygen, which is excited by dissociative recombination of O_2^+ ions or by soft electron precipitation. With a radiative lifetime of 110 s, the ^1D atoms may be expected to take up the neutral air velocity so that the doppler shift of their radiation should correspond to the neutral air wind velocity. The technique is now well-established for measurements of nighttime thermospheric winds at mid-latitudes^{1,2}; more recently the Mawson Institute group in Australia has reported daytime measurements of thermospheric winds with the technique, obtained despite the intense background of scattered solar radiation³.

This optical technique has the drawback that the radiation originates over a range of height, within which the wind velocity may vary considerably. This problem may be real for the thermally-driven winds at lower latitudes; but in the polar thermosphere (as discussed later) the wind is mainly driven by a large-scale electric field which is almost height-independent above 200 km,

Henry Rishbeth is at the Appleton Laboratory, Slough.

below which there is little 630 nm emission. There might be localized winds in the vicinity of active auroral forms, but most of the Spitzbergen observations were not made in such conditions. The height variation of 630 nm emission can to some extent be studied by using a limb-scanning interferometer carried in a satellite, for example OGO-6 (ref. 4); but only at the expense of horizontal resolution which is several hundred kilometres, at best. The satellite technique does however give the benefit of global coverage, within orbital limitations.

Smith and Sweeney's observations were made in the polar cap, a region usually about 30° in diameter, bounded by the 'auroral oval'⁵ in which auroral phenomena occur. Their results confirm a picture of polar thermospheric winds that has hitherto been based partly on observations by various techniques and partly on theory. Kohl and King⁶ first described the dayside-to-nightside winds across the polar cap that would result purely from heating of the dayside thermosphere by solar extreme ultraviolet (EUV), taking into account the effects of coriolis force and ion-drag (friction between ions and neutral air) on the wind direction. However, intense localized heating in the auroral oval — due partly to particle precipitation but mainly to joule heating by auroral electric currents^{7,8} — must modify the solar-driven wind pattern. Further modification results from electric fields, which at heights above 150 km produce Hall drift of the plasma ('E × B' drift), the horizontal component of this drift being imparted by ion-drag to the neutral air^{9,10}. This electrically-driven wind can be suppressed by 'back pressure' if it creates accumulations or depletions of air anywhere¹¹; however, in the polar cap the wind is nearly divergence-free and little 'back pressure' should occur¹².

The high-latitude electric fields comprise, first, intensive fields of magnetospheric origin, more or less localized in the auroral oval and peaking during substorms, and second, the

extensive dawn-to-dusk field in the polar cap that derives from the streaming of solar wind past the magnetosphere. The latter causes a dayside-to-nightside flow of ionospheric plasma across the polar cap, forming part of a great convective system with return flows at somewhat lower latitudes^{13,14}.

This 'plasma convection' has been studied in some detail by tracking chemical tracers released from rockets^{15,16}, by satellites such as Atmospheric Explorer¹⁷, and by incoherent scatter radars¹⁸; while the associated electric fields has been measured from balloons¹⁹. Smith and Sweeney's data show that the neutral air moves in a similar way to the plasma, at least for the winter conditions they studied. Around midday and midnight, the directions could probably be fitted by the Kohl and King theory⁶ based on solar EUV heating, but the convection theory¹⁵ accounts much better for the wind directions in the morning and evening sectors.

There remain many interesting problems to be resolved, not least the effect of the interplanetary magnetic field configuration on the plasma convection¹⁹. As to forthcoming activities, the previously-mentioned effects of auroral electric fields and joule heating will be intensively studied in the international campaign aimed at quantifying the upper atmosphere's energy budget, to take place in Scandinavia in winter 1980/81. Auroral motions will be increasingly studied with coherent radars such as STARE (the Scandinavian Twin Auroral Experiment). The European Incoherent Scatter (EISCAT) radar will come into operation in Northern Scandinavia and plans exist for upgrading the radar at Millstone Hill (Massachusetts) and moving the Chatanika (Alaska) radar to Greenland. Moreover, the Antarctic thermosphere differs significantly from the Arctic — largely because of the different magnetic field geometry — and future investigations may increasingly be directed southward. □

Response of plants to sulphur dioxide

from J. N. B. Bell

RECENT years have seen a reduction in the levels of SO₂ that are generally believed to inhibit plant growth. Previously it was commonly accepted that reductions in growth only occurred when relatively high concentrations ($\geq 500 \mu\text{g m}^{-3}$) caused visible injury to the foliage. It is now clear that the atmosphere in some sites where the mean SO₂ level is typical of many parts of Britain can substantially reduce the growth of grass species without any obvious symptoms on the leaves (Crittenden & Read *New Phytol.* **83** 645; 1979). Much air pollution research now concentrates on fumigation experiments designed to simulate such low SO₂ concentrations over prolonged periods and is aimed at quantifying the economic impact on vegetation of the 5.8×10^6 tonnes of SO₂ emitted annually in the United Kingdom. In practice it has proved difficult, even for the most intensively studied species, *Lolium perenne* (perennial ryegrass), to establish clear dose-response relationships and furthermore, different groups of workers have produced contradictory results with similar doses of SO₂ (see Bell *et al. New Phytol.* **83**, 627; 1979).

It is becoming increasingly apparent that the results of air pollution experiments are influenced considerably by environmental conditions within the fumigation chambers and there is circumstantial evidence that

slow growth enhances the toxic action of SO₂ (Bell *et al. op cit.*, 1979; Cowling & 'Lockyer *J. exp. Bot.* **108**, 257; 1978). Davies (this issue of Nature, page 483) provides the first unequivocal evidence that environmental conditions causing slow growth can interact with a moderate level of SO₂ to reduce yield.

Phleum pratense (timothy) was fumigated with $343 \mu\text{g m}^{-3}$ SO₂ for 5 weeks under two light regimes, representing summer and winter conditions, respectively. The SO₂ treatment caused a 50% reduction in dry matter compared with clean air controls under the winter conditions, but no effect under the summer light regime. Davies points out that many fumigation experiments are conducted under optimum growth conditions and that extrapolation to the field where there are marked environmental fluctuations, must be treated with caution.

Much of the early work with SO₂ was done in chambers with low rates of air movement, in which relatively high concentrations of SO₂ were reported to be harmless to plants. Ashenden and Mansfield (*J. exp. Bot.* **28**, 729; 1977) questioned the validity of these experiments, by demonstrating the importance of wind-speed in controlling uptake of SO₂ by vegetation. Using wind tunnels, they showed that $315 \mu\text{g m}^{-3}$ SO₂ reduced growth at a wind-speed of 25 m min⁻¹, but not at 10 m min⁻¹. They suggested that the lack of effect at the low wind-speed was caused by a failure to overcome the

boundary-layer resistance, so reducing the flux of SO_2 to the leaf surface. At the higher wind-speed, which is more representative of field conditions, the boundary-layer resistance was overcome and the stomatal resistance became the main factor controlling SO_2 uptake.

Another problem in fumigation experiments arises from the difficulty in defining and simulating the most important characteristics of ambient air pollution. Most experiments have used a constant concentration of SO_2 , but it is possible that occasional short-term peaks, which occur in the field, may be responsible for yield reductions observed at mean ambient concentrations which are not generally considered toxic. Furthermore, the presence of other pollutants in ambient air may have positive or negative interactions with the effects of SO_2 on plant growth. Thus Brough *et al.* (*Chem. Ind.*, 21 Jan; 1978) reported a 40% reduction in grain dry weight of barley raised in chambers ventilated with ambient air containing a mean concentration of $61 \mu\text{g m}^{-3} \text{SO}_2$, compared with clean air. The proximity of a large brickworks to their experimental site probably resulted in occasional peaks of SO_2 considerably in excess of the mean, as well as the presence of atmospheric fluoride pollution.

Few attempts have been made to relate physiological effects of SO_2 to growth reductions in the field. Recently, Black and Unsworth (*J. exp. Bot.* 114, 81; 1979) have shown that only $50 \mu\text{g m}^{-3} \text{SO}_2$, a level characteristic of many rural areas, can induce reductions in net photosynthesis

and changes in stomatal resistance of *Vicia faba* (broad bean). They have further demonstrated (*J. exp. Bot.* 116, 473; 1979) that the reduction in net photosynthesis at low irradiances was independent of SO_2 concentration. On this basis it was predicted that a fully developed canopy of *V. faba*, in which the lower leaves are shaded, would show a fairly similar reduction in dry matter production, irrespective of SO_2 concentration within the range $100\text{--}500 \mu\text{g m}^{-3}$. This emphasizes the importance of a clear understanding of the influence of SO_2 on whole crop physiology when predicting effects in the field.

Work during the past decade has laid the foundations for the understanding of the long-term effects of low concentrations of SO_2 on the growth of plants and the various factors which may modify these. However, the economic impact of SO_2 injury on plants remains uncertain. There is clear evidence for the stimulation by SO_2 of plant growth on sulphur deficient soils (Cowling & Lockyer, *op. cit.*) and for the evolution of SO_2 tolerance in grass populations in polluted areas (Horsman *et al.*, *J. exp. Bot.* 30, 495; 1979). Research during the next 10 years should be aimed at quantifying the importance of SO_2 or crop growth in areas with different pollution characteristics. Field investigations must be backed up by laboratory fumigations, which should closely simulate the ambient situation with respect to climatic conditions, realistic fluctuating levels of different mixtures of pollutants, and normal practice in crop cultivation. □

reconstructed as an extensive structure like that of bats, involving also the hind limbs and tail, and the weak flight muscles would have been quite inadequate to flap this wing. Physiology and structure combined to suggest a clumsy creature that could only have soared on its great flight membranes. Furthermore, pterosaurs also seemed to have been condemned to a perpetually wandering Flying Dutchman existence, for their weak hind-limbs made it difficult to understand how they could have risen into the air once they had landed.

Research over the past 10 years has overturned all these assumptions and, though many problems remain, pterosaurs now seem rather more comprehensible. Earlier workers had seen hair-like markings on the body, but it took the discovery of a much better-preserved specimen (Sharov *Trudy pal. Inst. Akad. Nauk. SSSR* 130, 104; 1971), together with a much more open-minded approach to the physiology of extinct reptiles, before it became respectable to consider the possibility that pterosaurs were insulated and, perhaps, homiothermal.

Studying the skeletons and wing-impressions of the smaller pterosaurs, known as pterodactyls, Wellnhofer (*Abh. bay. Akad. Wiss.* 141, 1; 1979) showed that there was no evidence that the wing was attached to the hind foot. He therefore restored the wing with a much narrower, bird-like outline (see illustration), and Padian (*Discovery* 14, 20; 1979) has recently shown that, if the estimated body-weight of a pterosaur is compared with the body-weight : wing area relationships of living animals, the results also suggest a smaller, more slender flight membrane. Such a wing, freed from attachment to the hind limb, is obviously more manoeuvrable in flight and less cumbersome when the wing is folded and the animal is moving on the ground. Wellnhofer also dismisses the belief that there was a flight-membrane between the hind legs and the tail. The resulting slim-line pterosaur will necessitate the reworking of previous calculations on their wing-loading and aerodynamic capabilities (for example Bramwell & Whitfield *Phil.*

Trimming the pterosaur's wings

from Barry Cox

THE old-fashioned view of the extinct flying reptiles known as the pterosaurs seemed reasonably consistent. Being reptiles, they were 'obviously' cold-

blooded. The lack of any high keel running along the sternum suggested weak wing muscles. The flight membrane, borne on the arm and elongated fourth finger, was

Wellnhofer's reconstruction of the pterodactyl *Rhamphorhynchus*. Wing span 1 metre.

THE recent papers by Gleadow (*Nature*, 284, 225; 1980) and McDougall *et al.* (*Nature*, 284, 230; 1980) may have ended a decade of controversy over the age of the KBS tuff in the East Turkana region of Kenya. The KBS tuff is critical to the dating of Early Man and his tools in this important anthropological site. Efforts to date this tuff provide a fascinating and instructive case history of geochronology which illustrates the process of trial and error by which science progresses. Some of the highlights of this case history are sketched below.

The KBS tuff lies near the middle of the Koobi Fora Formation, which yielded its first hominid fossils to Richard Leakey's expedition in 1968. By 1973, 110 hominid fossils had been collected. Primitive artefacts were discovered in 1969, and two occupation sites were excavated in the KBS tuff by Isaac *et al.* (*Science* 173, 1129; 1971). Feldspar from the tuff was dated by Fitch and Miller (*Nature*, 226, 226; 1970) both by the conventional (total degassing) K-Ar method and by the newly developed $^{40}\text{Ar}/^{39}\text{Ar}$ step-heating method. The conventional method produced a wide scatter of ages, clearly in part because of contamination by older feldspar. An age of 2.61 ± 0.26 Myr was assigned to the tuff on the basis of the $^{40}\text{Ar}/^{39}\text{Ar}$ age spectra. Dates younger than 2.6 Myr from the conventional method were believed to reflect argon loss caused by regional hydrothermal alteration.

Doubt about the date of 2.6 Myr was raised by some palaeontologists, who found an age of 2 Myr more in accord

R. L. Hay is Professor in the Department of Geology and Geophysics, University of California, Berkeley.

The KBS tuff controversy may be ended

from R. L. Hay

with dated faunas at Olduvai Gorge and the Shungura Formation in the Omo basin (Cooke & Maglio in *Calibration of Hominoid Evolution* (eds Bishop, W. E. & Miller, J. A.) 303, Scottish Academic Press; 1972). The palaeomagnetic stratigraphy of the Koobi Fora Formation was now studied by Brook and Isaac (*Nature* 234, 344; 1974) with the object of dating the strata by matching their polarity with the newly established polarity time scale. They found two possible fits with the polarity scale, one of which was compatible with the KBS tuff date of 2.6 Myr. Curtis *et al.* (*Nature*, 258, 395; 1975) added to the controversy by reporting K-Ar dates of 1.60 Myr for the KBS tuff at one locality and 1.82 Myr from the tuff at another locality. Their results were particularly significant because dates on feldspar and glass were concordant, thus providing strong evidence against loss of radiogenic argon. If their results were accurate, the KBS tuff must be in fact two tuffs, separated in time by 200,000 years.

Next, zircons from the KBS tuff were dated by the fission-track method. The zircons contained low fission-track densities, but an age of 2.44 ± 0.08 Myr was obtained by Hurford *et al.* (*Nature* 263, 738; 1976). Fitch *et al.* (*Nature* 263, 740; 1976) recalculated their step-heating results and now suggested 2.42 Myr as the best K-Ar age.

In 1977 Harris and White (*Science* 198,

13; 1977) concluded from their studies of suid evolution that deposits below the KBS tuff were equivalent to fossiliferous beds in the Omo basin and Olduvai Gorge that had been dated at about 1.8 Myr. Hillhouse *et al.* (*Nature* 265, 411; 1977), in another palaeomagnetic study of the Koobi Fora Formation, found that although two correlations were possible with the polarity time scale, placing the KBS tuff in the Olduvai normal event (~ 1.7 – 1.85 Myr) created fewer difficulties in the geological history than did an age of 2.4 Myr for the tuff.

Cerling *et al.* (*Nature*, 279, 118; 1979) now correlated the KBS tuff with tuff H₂ (~ 1.8 Myr) of the Shungura Formation on the basis of chemical composition of glass and feldspar. This correlation received strong support from additional dating of the KBS tuff by Drake *et al.* (*Nature* 283, 368; 1980). They gave an age of 1.8 ± 0.1 Myr for the tuff, and explained that the date of 1.60 Myr reported earlier for the tuff at one locality was incorrect because of an error in K analyses.

The latest and perhaps the final statements on the age of the KBS tuff are provided by McDougall *et al.* Their meticulous K-Ar dating of feldspar gave an age of 1.89 ± 0.01 Myr. Fission-track dating by Gleadow yielded an age of 1.87 ± 0.04 Myr, and made a notable contribution to the methodology of fission-track dating of zircons which contain low track densities. In closing, it should be emphasized that the KBS tuff has been a testing ground for various geochronologic methods, both new and old, and the science of geochronology has learned much from the "KBS tuff controversy."

Trans. R. Soc. B 267, 503; 1974). These studies have involved the great albatross-like soaring pteranodontids of the Cretaceous, such as a 7 m wing-span *Pteranodon*, but even this is dwarfed by *Quetzacoatlus* from Texas, the humerus of which is 70% longer than that of *Pteranodon*, and which may have had a wing span of 15 m!

Modern workers seem agreed that the smaller pterosaurs, at least, were actively-flapping fliers, and it now appears that there was, after all, a strong ventral keel projecting forwards from the sternum, which was itself also strongly braced from the scapula by powerful coracoid bones, very much as in birds.

The freeing of the hind-limb of pterosaurs from the flight membrane also helps in the interpretation of their method of launching themselves into the air. Wellnhofer (*Palaeontographica* A149, 1; 1975) believes that the hind-limbs could at least have raised the body into the air far enough that, facing into the wind, the outstretched wings could lift the body from the ground, and that the hind-limb could

also have helped to thrust it skywards.

But further problems arise from the diet of pterosaurs. Both their common presence in marine deposits, and their preserved stomach contents, show that most of them fed on fish. Wild has most recently discussed the problems of the method they used to catch their prey (*Boll. Soc. pal. Italiana* 17, 176; 1978). Though some living birds catch fish from near the water surface by flying close above it, Wild points out that pterosaurs must have been far less competent aerodynamically. This, together with their proportionately much longer wings, would make it inevitable that a wing-tip would sooner or later hit the water, bringing the whole creature down into the sea. Wild also argues that the braking effect of dipping the beak into the water to catch fish would cause such a drop in speed as to bring the pterosaur down. He instead believes that they fished by folding their wings and diving into the water. (This would inevitably have placed considerable strain on their skull and skeleton, and it

Barry Cox is Professor in the Department of Zoology, Kings College, London.

would be instructive to investigate whether they show any convergences with the adaptations of living diving birds such as gannets.)

There is evidence that the hind feet of pterosaurs were webbed and they must have used these for swimming, whether their immersion was voluntary or accidental. Wild thinks it possible that they might have been able to rise from the water surface by spreading their wings, or that they might instead have swum to nearby land so as to rise from a solid surface. (Could it be that the hairy covering had a water-repellent function?)

The pterosaurs which Wild describes come from the Late Triassic and include members of two different families. The origin of the group as a whole must therefore lie in the earlier Triassic at least. Wild points out that the whole organization of the early pterosaurs suggests derivation from a small running and climbing insectivorous reptile. He believes that this strongly suggests that they evolved from the little eosuchians of the Late Permian and Early Triassic, rather

than from the larger terrestrial carnivorous pseudosuchians, most of which were in any case too late in time to be potential ancestors.

Though some problems have then, at

least been tackled, one still cannot help feeling that just as a camel is said to be a horse designed by a committee, the pterosaur is the result of that committee turning its attention to birds. □

Fish vision discussed

from a Correspondent

THE thirty thousand or so living species of fishes inhabit a wider variety of visual environments than any other vertebrate group. Different water bodies vary widely in their colour and turbidity, presenting very different visual tasks to their inhabitants; many species migrate during their life span exposing themselves to these various environments; and there are also often marked seasonal changes in the water's quality. The fishes, therefore, form an ideal group for comparative studies of vision. If we add to this the fact that they are readily available and excellent subjects for physiological experiments, it is not surprising that a great deal of work has been done on various aspects of their vision. Some was reported at a recent meeting of the British Photobiology Society held in London*.

Anatomical papers on the retina (H.-J. Wagner, Universität Ulm) and on cone photopigments (J.N. Lythgoe, University of Bristol) made full use of the comparative approach, and showed that striking differences, clearly associated with the environment, may be found. Explaining their significance is, however, often more difficult. Why, for example, should fish living near the surface be less sensitive to long wavelength light than those that live deeper? They clearly are, though no one knows the reason.

K.H. Ruddock (Imperial College, London) presented results from experiments involving strong bleaching of the retina with a laser, a technique that can reveal receptor interactions that are normally concealed. R. Weiler (Universität München) then described his results on horizontal cells, which posed the unanswered conundrum of how a graded potential can be transmitted without degradation along 600 µm of axon when theoretical considerations suggest 150 µm should be the maximum possible distance. M.B.A. Djamgoz (Imperial College, London) and S.H. Reynolds summarized their work on possible retinal transmitter substances. A wide variety of possible transmitters exist: a list of some 30 candidates was given, of which the most likely ones are GABA and aspartate. Although, however, the evidence is very suggestive, even in these cases it is not conclusive and much work, which should

prove very profitable, clearly remains to be done.

These retinal studies used fish mainly because of their experimental convenience. Reports on the anatomy and physiology of the optic tectum followed in which fish were also used largely for this reason. In the complex analyses that the tectum carries out, however, the problems of the aquatic environment also began to reappear. For example, tectal units responding in a most striking way to very short wavelength light were described for the perch, which is surprising in a fish that does not possess blue cones, has a yellow cornea, and lives in

coloured water in which short wavelength light is almost totally absent. Other units that respond preferentially to repeated stripes were described for this species: could these be related in any way to the fact that the perch itself is striped?

Two papers reported laboratory behavioural studies on spectral sensitivity in fish. W.R.A. Muntz (University of Stirling) reported data that compared vision in an upward direction with vision downward: these showed marked differences in both absolute sensitivity and the form of the spectral sensitivity curve, which may plausibly be related to the difference in the amount of light reaching the fish from the two directions. C. Neumeyer (Institut für Zoologie, Mainz) presented spectral sensitivity data for goldfish. One striking and confusing fact about behavioural studies is that whenever the experimental situation is changed the results also usually change, and these results were no exception to this rule. Presumably different neurones, with different sensory inputs, contribute preferentially to different behaviour patterns. □

Polarity of spindle microtubules

from Jeremy Hyams

UNLIKE microfilaments in which directionality can be visualised directly by specific interaction with heavy meromyosin, the polarity of microtubules has, until now, been approachable only by more devious methods. The most successful has exploited the ability of tubulin subunits with attenuated capacity to self-assemble, to polymerize *in vitro* onto some preformed seed or organizing centre. Various cellular structures will apparently serve although most frequently used are flagellar axonemes from the green alga, *Chlamydomonas*, whose two ends are morphologically distinguishable. When axonemes are incubated with low concentrations of brain tubulin (<2 mg ml⁻¹), microtubules grow by the addition of subunits onto the distal end only. At higher tubulin concentrations, growth is onto both ends of the axoneme although the rate of subunit addition at the distal end is at least three times that at the proximal (Allen & Borisy *J. molec. Biol.* **90**, 381; 1974; Binder *et al. Proc. natn. Acad. Sci. U.S.A.* **72**, 1122; 1975). This directional polymerization is taken to reflect an intrinsic molecular polarity within the microtubule structure, that is, the asymmetric tubulin subunits are all oriented in the same way along the microtubule axis, an arrangement also inferred from detailed analyses of microtubule structure by electron microscopy and optical diffraction (Amos & Klug *J. Cell Sci.* **14**, 523; 1974).

Microtubule polarity has been a central concern in studies of mitosis ever since a suggestion made over a decade ago by McIntosh, Hepler and van Wie (*Nature* **224**, 659; 1969), that the polar functions of the mitotic spindle in mammalian cells might reflect an antiparallel relationship of microtubules originating from the polar centrosomes and the chromosomal kinetochores. The subsequent demonstration by many workers that both of these components would nucleate the assembly of neurotubulin in cell-free systems (McGill & Brinkley *J. Cell Biol.* **67**, 189; 1975; Snyder & McIntosh *J. Cell Biol.* **67**, 744; 1975; Telzer *et al. Proc. natn. Acad. Sci. U.S.A.* **72**, 4023; 1975) appeared, at least superficially, to be consistent with the McIntosh *et al.* model.

A more recent series of papers from Margolis and Wilson, however, has struck a discordant note. On the basis of an analysis of the exchange of [³H]GTP with microtubules assembled to steady state, these workers have proposed a novel mechanism of microtubule assembly whereby subunits are added to one end of the microtubule and removed at the other in a unidirectional (opposite end) assembly and disassembly process (*Cell* **13**, 1; 1978). The result is a continuous flow, or 'treadmilling' of subunits along the microtubule at a rate measured to be 0.69 µm h⁻¹. Extrapolation of these findings to

Jeremy Hyams is in the Department of Botany and Microbiology, University College, London.

*The Visual System of Fish, organized by M.B.A. Djamgoz (Imperial College, London) was held at Imperial College on 27 February, 1980.

the microtubules of the mitotic spindle has yielded a picture of spindle organization which differs radically from that outlined above (Margolis *et al.* *Nature* **272**, 450; 1978). Briefly, Margolis *et al.* envisage that microtubules assembled at the poles grow by the addition of subunits at the end distal to the organizing centre, while those assembled at the chromosomes are extended by the insertion of subunits proximal to the kinetochore. The result is a spindle in which the microtubules reveal a parallel orientation either side of the equator. Such an arrangement is not without appeal. The continuous insertion of subunits to both chromosomal and polar microtubules in the equatorial region and their subsequent removal at the poles might be expected to produce a constant poleward migration of material, a phenomenon often seen in the spindles of living cells. Although the measured rates of subunit treadmilling *in vitro* are generally lower than motions associated with living spindles, more recent work from the same laboratory has shown that the *in vitro* rate can be increased some 20-fold by the addition of 1 mM ATP to their assembly soup, giving a rate more consistent with that *in vivo* (Cell **18**, 673; 1979).

Unfortunately for such an elegant concept, the model was destined for a relatively short half-life, a situation by no means without precedent in the mitosis literature. Its demise was signalled by the appearance of two papers from the University of Wisconsin (Bergen & Borisy *J. Cell Biol.* **84**, 141; 1980; Bergen *et al.* *J. Cell Biol.* **84**, 151; 1980). Following an earlier suggestion from the same laboratory (Borisy *J. molec. Biol.* **124**, 565; 1978), these workers have undertaken a detailed analysis of the kinetics of polymerization and depolymerization of microtubules initiated *in vitro* by the centrosomes and kinetochores of Chinese hamster ovary cells. As a unique added refinement, Bergen and his colleagues have included in their analysis, *Chlamydomonas* flagellar axonemes as an unambiguous internal marker of directional microtubule growth. Thus it was possible to determine whether microtubules assembled onto the spindle organizers did so at a rate equivalent to that seen at either the proximal or distal ends of the flagellar standards alone, or alternatively at a rate which was a summation of the two reactions. The results were unequivocal. The rate of assembly into the mitotic organizers was identical to that at the distal end of the axoneme only, irrespective of whether conditions also supported the proximal extension of the internal standard. Equally important, a corresponding survey of the rate of depolymerization showed that this too was equivalent solely to the reaction taking place at the distal end of the added axonemes. Both findings conflict with the view of the spindle proposed by Margolis *et al.* in several important respects. Both

polar and chromosomal microtubules grow by addition of subunits distal to their site of initiation. Their arrangement in each half of the spindle must consequently be antiparallel. Finally, addition and removal of subunits takes place at the same, and not opposite, ends of the microtubule.

Intriguing as these assembly studies might be, there are encouraging signs that their days as the sole experimental handle on microtubule directionality are numbered. An exciting paper by Haimo, Telzer and Rosenbaum (*Proc. natn. Acad. Sci. U.S.A.* **76**, 5759; 1979) suggests that the long-awaited morphological marker of microtubule polarity might at last be at hand. The candidate is dynein, the ATPase protein responsible for the movement of cilia and flagella and seen as paired projections, or arms, connecting the 9+2 microtubules. Haimo and her colleagues have shown that axonemal dynein from *Chlamydomonas* added to microtubules during or subsequent to assembly binds periodically along the length of the microtubule, forming a complex reminiscent of the 'decoration' of

microfilaments by heavy meromyosin. The centre-to-centre spacing of the dynein projections is 24 nm, the same as its periodicity in the flagellum from which it derives. More important, when these reconstituted dynein arms were examined in the electron microscope they were characteristically tilted when viewed in longitudinal section and hooked when seen in transverse profile. Thus the arms can be used to define microtubule polarity in either orientation.

Although it is a long step from these *in vitro* studies to the *in situ* decoration of microtubules like those of the mitotic spindle, such an application might prove to be particularly appropriate. The anaphase movement of chromosomes in lysed mammalian cells has been shown to depend on the presence of ATP (Cande *et al.* *Proc. natn. Acad. Sci. U.S.A.* **71**, 573; 1978). Whether dynein is eventually shown to be the force-generating component of the spindle remains to be seen. What is clear is that this protein is going to have a central role in an exciting new era of microtubule research. □

The metal-semiconductor contact

from D.C. Northrop

METAL-semiconductor contacts (Schottky barriers) are commonplace in modern semiconductor electronics. Not only do they perform the active function of rectification in devices as widely different as microwave detectors and high current rectifiers, but they serve as ohmic contacts to virtually every semiconductor device that is made. Because of their evident importance such contacts continue to provoke widespread research interest on two quite separate fronts. One of these concerns the yield and reliability of semiconductor devices and microcircuits, where the metal-semiconductor contact and its associated metal wire bond are the most fallible part of the whole system. The other area of research, and the one that concerns us here, is the search for understanding of the physics of the contact; the relationship between its electrical properties and its structure.

Historically, the earliest attempt to provide a physical model for potential barrier formation was that commonly attributed to Schottky (Schottky *Naturwissenschaften* **26**, 843; 1938), but more correctly credited to Mott (Mott *Proc. Cambridge Phil. Soc.* **34**, 568; 1938) in the form in which it is usually stated. This model proposes that the electrostatic potential barrier opposing electron flow from the semiconductor to the metal is equal to the difference between the work

functions of the metal and the semiconductor making up the contact. This has an elegant simplicity about it and held sway for many years, partly because work functions are notoriously hard to measure experimentally, making the theory difficult to check. The first workers to provide adequate experimental results for metal contacts to clean silicon were Allen and Gobeli (*Phys. Rev.* **127**, 150; 1962) who found barrier heights that were essentially independent of the work function of the metal, apparently confounding the theory. Their results led to the acceptance of an idea proposed earlier by Bardeen (*Phys. Rev.* **71**, 717; 1947). He added to the Mott-Schottky model the concept of surface states; localised energy levels at the surface, whose electron occupancy had a controlling effect on the electric field in the semiconductor. This allowed a qualitative explanation of Allen and Gobeli's results, and also accounted for the great variability of other less carefully obtained experimental data.

Then followed the longest and most difficult phase of the work. Experimental techniques improved in every way; better vacuum systems, a greater number of very pure metals and semiconductors and more sensitive measuring techniques have all contributed to the search for these elusive surface states. Theoretical physicists have been at work too, and have played an important part in guiding experimental work. Particularly influential in this area have been Heine (*Phys. Rev.* **138A**, 169; 1965) and Inkson (*J. Phys. C*, **6**, 1359;

D.C. Northrop is in the Department of Electrical Engineering and Electronics, University of Manchester Institute of Science and Technology.

1973), who pointed out that when metal and semiconductor are placed in intimate contact their surfaces will both be changed, particularly by the ability of electrons to penetrate from the metal into the surface of the semiconductor by tunnelling into the forbidden energy gap. This effect changes the charge distribution and therefore the electric field at the interface in a way that could explain qualitatively quite a large body of results. Gradually it has become clear, however, that quantitatively the effects predicted are not large enough to explain the number nor the spatial distribution of surface states. The results of Thanailakis (*J. Phys. C*, **8**, 655; 1975), are amongst the most important in establishing this point.

We come now to the latest suggestion, backed by extensive and impressive experimental data from Spicer and his group at Stanford University. The latest paper (Spicer *et al. Phys. Rev. Lett.* **44**, 420; 1980) spells out the mechanism they propose for barrier formation in a number of compound semiconductors. These are materials which exhibit no intrinsic surface states within the forbidden energy gap. That is, on the cleaved surfaces of these materials the Fermi Energy is found, by

photoelectric emission measurements, to be the same as that in the bulk, showing that there is no electric field in the semiconductor surface. The evaporation of metal, or the adsorption of oxygen, on these surfaces is found to change this situation and to give rise to surface states and, consequently, to electric fields which move the band edges relative to the Fermi Energy. The most important feature of their results is that the energy levels so produced are specific to the semiconductor and not to the material deposited. Spicer's explanation of this depends on the large heat of adsorption of materials on semiconductor surfaces, about 3 eV per atom according to some measurements. This is enough to produce lattice defects such as vacancies or more complex entities in and near the semiconductor surface, and it is these defects, Spicer claims, which control the potential barriers. It is perhaps early to say that the full picture has now been revealed, but it is clear that an important new step has been taken. It will lead to a better appreciation of what is possible in the production of metal-semiconductor contacts with tailored properties as well as improving our understanding of interface physics. □

virus equivalent of SV5-induced HN antibodies), and would provide additional antigenic stimulation resulting in an anamnestic response to the H antigens to which the vaccine provided the primary response. In these conditions, immune complexes composed of the antigen-producing syncytium and H antibodies could form, activate the complement system and result in inflammation and tissue necrosis. Alternatively, antibody-mediated cytotoxicity might cause the observed inflammation without complement activation. Either process could account for the immunopathological reactions that have been observed in some people given RS or measles vaccines.

In addition to providing an insight into the possible mechanisms involved in the complications associated with paramyxovirus vaccination, the work of Merz *et al.*, together with earlier work by Waldman and Ganguly (*J. infect. Dis.* **130**, 419; 1979) and McIntosh *et al.* (*J. infect. Dis.* **138**, 24; 1978), among others, suggests an approach to paramyxovirus vaccination that may be both safe and effective. Merz *et al.* show that pure F glycoprotein would be the ideal immunogen for a paramyxovirus vaccine and the earlier studies suggest that the most effective way of administering this immunogen would be directly into the lung as an aerosol. The advantage of such local immunization is that it would stimulate secretory IgA, which does not activate the complement system or antibody-mediated cytotoxicity, and would thus avoid the immunopathological consequences resulting from stimulation of IgG antibodies. The disadvantages of the suggested approach are the difficulty of developing high IgA titres and the short duration of immunity. However these problems are not insurmountable. Morein *et al.* (*Nature* **276**, 716; 1978), for example, were able to prevent a lethal infection of mice with Semliki Forest virus by vaccinating the mice with a micellar aggregate of the virus spike protein. Interestingly, they found that the monomer form of the protein solubilized with detergent was much less effective than the aggregated protein. Those results suggest that protective and lasting immunity to paramyxoviruses might be stimulated by administering the F glycoprotein as an aggregate rather than in the solubilized form. Alternatively, the F glycoprotein could be administered together with an immunoadjuvant, such as the purified active component of Freund's adjuvant, N-acetyl-muramyl dipeptide (Azuma *et al. Infect. Immun.* **14**, 18; 1976; Chedid *et al. Proc. natn. Acad. Sci. U.S.A.* **73**, 2472; 1976), which does not produce the abscesses associated with the complete Freund's adjuvant. Using either approach, it might be possible to introduce pure F glycoprotein into the lung as an aerosol and stimulate immunity without adverse side effects. If so, it would be an important step towards controlling respiratory infections.

Vaccination against paramyxoviruses

from A.J. McClelland

PARAMYXOVIRUSES are now known to be a major cause of respiratory illnesses but, despite the importance of these diseases, little progress has been made in their control. Live virus vaccines are available for only two paramyxovirus diseases (measles and mumps) and failures of these vaccines resulting in severe complications, such as modified and atypical measles, have been reported (Chatterji & Marikad *J. Am. Med. Assoc.* **238**, 2635; 1977). Inactivated virus vaccines against the measles virus and other paramyxoviruses, such as the respiratory syncytial (RS) virus and the parainfluenza viruses, have had limited success and have sometimes induced severe forms of the illnesses they are supposed to prevent (Kim *et al. Am. J. Epidemiol.* **39**, 422; 1969; Welliver *et al. Arch. Int. Med.* **137**, 39; 1977). The unusual complications that sometimes occur after paramyxovirus vaccination have been attributed to an aberrant immune response, but it is not known how or why such a response occurs.

New light has recently been shed on the problems associated with paramyxovirus vaccination by Merz *et al.* (*J. exp. Med.* **151**, 275; 1980) who have investigated the infectious spread of one paramyxovirus, SV5, using monospecific antibodies to the two SV5 surface glycoproteins. These

authors report that SV5 can be disseminated in two ways: (1) release of infectious virus from infected cells and (2) cell fusion, in which no infectious virus need be released. They found that antibodies to the viral haemagglutinating and neuraminidase (HN) glycoprotein prevent the spread of infection by the release of virus particles, but do not prevent the spread of infection by cell fusion, whereas antibodies to the viral fusion (F) glycoprotein prevent the spread of infection by both cell fusion and release of infectious virus. The results obtained by Merz *et al.* emphasize the importance of the F glycoprotein in the dissemination of SV5.

Their findings, together with the earlier observation that vaccination elicits a weak F antibody response, or fails to stimulate F antibody production altogether (Norrby & Gollmar *Infect. Immun.* **11**, 231; 1975), suggest a possible explanation for the severe complications that sometimes result from paramyxovirus vaccination. In a person vaccinated against measles, for example, exposure to the measles virus could result in a disseminated infection because of the lack of F antibodies and the ability of the virus to spread from cell to cell by cell fusion. As the infection spreads, syncytium formation would take place and the antigen load would increase. Released virus particles would be neutralized by the vaccine-induced H antibodies (the measles

REVIEW ARTICLE

Fluorescently labelled molecules as probes of the structure and function of living cells

D. Lansing Taylor & Yu-Li Wang

Department of Cell and Developmental Biology, Harvard University, 16 Divinity Avenue, Cambridge, Massachusetts 02138

A new approach to cell biology has been created by combining the techniques of micromanipulation of cells, fluorescence spectroscopy and low level light detection. These methods are now being used to study the spatial and temporal distribution, interaction and activity of specific molecules in living cells.

CELL functions such as locomotion, cell recognition, endocytosis, exocytosis, and cell division involve highly dynamic and transitory molecular interactions. Early cell physiologists studied these functions by probing living cells and developed sophisticated techniques for micromanipulation and microinjection¹⁻⁴. A new approach bridging the gaps between cell physiology, biochemistry and ultrastructure is required to define the molecular mechanisms of complex cell functions. Such an approach would require a combination and coordination of (1) techniques for manipulating living cells, (2) techniques which provide signals from specific molecules with high sensitivity, and (3) techniques which detect weak signals from living cells. Recently, the methods of micromanipulation of cells¹⁻⁵, fluorescence spectroscopy⁶⁻⁸, and low-level light detection⁹⁻¹³ have been combined to provide such a new approach to cell biology. This new concept involves labelling purified molecules covalently with fluorescent probes, and incorporating the fluorescent conjugates into or onto living cells. Cells with associated fluorescent conjugates are then either viewed with an image intensifier coupled to a microscope or are investigated with a microspectrofluorometer. Therefore, the high sensitivity ($\sim 10^5$ – 10^6 molecules can be detected¹⁴), and versatility⁶⁻⁸ of fluorescence techniques can be fully utilised in living cells to yield information at the molecular level.

This review is limited to applications of this approach in which purified molecules are labelled, administered and then studied at the light microscopical level. The technical aspects will be discussed in detail since this new approach requires careful application and interpretation. In addition, three categories of fluorescent conjugates will be discussed: (1) nonperturbing indicators of physiological processes, (2) biologically active agents and (3) functional cellular components (molecular cytochemistry)¹⁵. Some of the studies referenced could be included in more than one of these categories.

Experimental methods

The application of fluorescent conjugates to studies in single living cells demands the use of highly fluorescent fluorophores which absorb in the visible spectrum, so that adequate signals are obtained while minimising radiation damage and interference from autofluorescence¹⁶. Furthermore, the conjugates must be associated by stable covalent bonds and be devoid of non-covalently bound fluorophores. Recent advances in the preparation of fluorescent reagents have provided several compounds suitable for applications *in vivo*. Fluorochromes such as fluorescein¹⁵⁻¹⁷, eosin¹⁸, 7-chloro-4-nitrobenzo-2-oxadiazole (NBD)¹⁹, and a series of long-wavelength rhodamine dyes^{15,20-21} have been used successfully with living cells. In addition, various reactive derivatives of these fluorophores such as iodoacetamide¹⁵, isothiocyanate²⁰ and sulphonyl chloride¹³ can be obtained commercially. Many of the long-wavelength

fluorophores used primarily by neurophysiologists should be useful when reactive derivatives become available²².

Classical microinjection techniques are still the most direct methods for incorporating exogenous components into living cells^{1,23}. Several different microinjection systems, using both hydraulic pressure^{4,5,17} and compressed air^{13,24,25}, have been described in detail. Cells ranging in size from giant protozoans ($\sim 600 \mu\text{m}$) to human fibroblasts ($\sim 15 \mu\text{m}$) have been successfully microinjected. These techniques are time consuming and the numbers of cells which can be studied are limited. However, they have the advantages that only a very small volume of material is required for each experiment; components as large as

Fig. 1 Autophagy studied by injecting highly concentrated tetramethylrhodamine isothiocyanate labelled bovine serum albumin into HeLa cells. These fluorescence micrographs were taken of injected cells *a*, immediately; *b*, 30 min; *c*, 1 h; *d*, 90 min; *e*, 6 h thereafter. The labelled proteins were taken up into vesicles which ultimately fused with lysosomes (*f*). (From Stacey, and Allfrey⁴⁵.)

organelles can be microinjected⁴, mild solution conditions can be used to deliver the fluorescent conjugates^{13,15,17,20}, and injection volumes can be controlled.

During the past few years, new delivery methods using fusion techniques have been developed. The molecules are trapped inside carriers such as red blood cell ghosts²⁶ and liposomes^{27,28} which are subsequently fused with target cells. While these methods allow the 'ultramicroinjection' of large populations of very small cells there are also several limitations: (1) relatively large volumes of fluorescent conjugates are required during the loading process, (2) the conjugates could become exposed to detergents, elevated temperatures, or organic solvents, (3) the proper entrapment and fusion steps must be carefully verified, and (4) the biological effects of the carriers must be controlled. Recently, fibroblasts have been successfully loaded with fluorescently labelled antibodies by red blood cell fusion techniques²⁹. Continued improvements in fusion technology should make these approaches more generally useful in the future.

Cell perfusion techniques have been used to deliver small ions and molecules into plant cells³⁰. A membrane permeation technique has now been reported which permits the incorporation of small molecules into living animal tissue culture cells³¹. The cells are permeabilised by short treatments with lysolecithin which make the cells leaky to exogenous molecules in the medium for a short period of time. This technique has advantages similar to those of fusion methods, yet does not require the use of carriers. Unfortunately, the application is limited to only very small molecules (molecular weight below 10,000) and to cells grown in monolayer culture. In addition, the cells remain viable for only a short period.

Recent developments in image intensification techniques have provided a more sensitive way of recording fluorescent images than classical photographic methods¹⁰. The use of standard photographic procedures requires long exposure times and intense illumination. Therefore, fluorescence photobleaching could be extensive, cell damage is possible, and dynamic processes are difficult or impossible to record. In contrast, TV image intensifiers coupled to fluorescence microscopes and video tape recorders allow the continuous recording of weakly fluorescent images in real time or time lapse without significant losses in resolution¹⁰. Some TV cameras also provide digital output for quantitative image analyses. When these intensifiers are coupled to optical prisms and multichannel analysers, they can also provide rapid microspectrofluorometric measurements^{10,32}.

Microspectrofluorometers have been developed for quantitative measurements of many fluorescence parameters with very low light intensities^{33,34}. In particular, photomultipliers

interfaced with single photon counting devices have provided instruments of high sensitivity³⁵. These systems in combination with computer-controlled spectral scanning and data processing form the core of several sophisticated microspectrofluorometers which are capable of performing corrected spectral measurements on single living cells³⁵⁻³⁸. The use of lasers for excitation has also increased the versatility of microspectrofluorometers, because the state of polarisation, spot size, duration and intensity of the exciting light pulse can be controlled over large ranges.

Recently, fluorescence photobleaching recovery techniques have been introduced to measure the mobility of surface associated fluorophores³⁹⁻⁴². These methods utilise a pulsed high-intensity laser microbeam to bleach a small area or volume of fluorescence, and the recovery of fluorescence is monitored with attenuated laser excitation. These measurements can yield diffusion constants of the mobile fraction, the percentage of fluorescent conjugates that are mobile, and information on the bulk directional flow of the conjugates. However, caution must be exercised in controlling the possible biological effects of photobleaching⁴³, and consideration must be given to the validity of the assumption that cell surfaces are flat and smooth. In addition, care must be taken to ensure that the membrane or surface markers are not internalised before making measurements. These potential problems have recently been addressed critically by Elson and Yguerabide⁴⁰.

Physical and chemical considerations

There are several possible physical and chemical problems which could give rise to experimental artefacts, and investigations using this new approach must be judged in part by the manner in which potential problems are considered. Factors which could affect the fluorescence intensity measured for the microscope include: (1) local accessible volume for the conjugate in the cell, (2) local environment of the conjugate, (3) optical properties of the microscope, and (4) local concentration of the conjugate.

Consideration of the local accessible volume is important for both cytoplasmic and membrane-associated components. For cytoplasmic components, the local accessible volume is controlled not only by the actual thickness of the cell, but also by the distribution of organelles which exclude the fluorescent conjugates. For membrane-associated components, the accessible volume is affected dramatically by the presence of membrane folds and microvillar structures. This problem can be

identified and controlled by using a second fluorescent conjugate which would distribute uniformly within the accessible volume. Labelled bovine serum albumin, ovalbumin, or denatured proteins have been used in controls for cytoplasmic components^{13,15,17,20} and fluorescent lipid probes⁴¹ can be used in studies on membrane-associated factors. It is imperative that co-incorporation of the experimental conjugate and the control conjugate labelled with a second probe be accomplished in the same cell when the cell shape is irregular¹³. Adequate comparisons cannot be performed in separate cells when they have irregular geometries. However, separate cells can be used when the cell geometry is reasonably constant and simple¹⁷.

The local environment around the fluorescent conjugate could also affect the fluorescence intensity by altering the quantum yield or fluorescence spectral properties. Local variations in ionic parameters such as pH and ionic strength as well as binding of other molecules to the conjugates could change the fluorescence parameters^{6,7}. The sensitivities of fluorophores can either be utilised in characterising microenvironments or they must be controlled when other parameters are under investigation. Controls for the ionic environments can be performed by comparing the fluorescence of the experimental conjugates with the fluorescence of separate cells containing nonspecific molecules (such as ovalbumin) labelled with the same fluorophore¹⁷, while controls for the effect of specific molecular interactions require the extrapolation of data from solution spectroscopic studies¹⁶.

Knowledge of the optical properties of the microscope is important for interpreting fluorescence images and quantitating local fluorescence properties. The characterisation of the fluorescence image *in vivo* depends on the depth of focus of the microscope. A large depth of focus in relation to cell thickness

optimises the formation of an in focus image of the whole cell, while a small depth of focus yields an optical section of the cell. The latter condition would require several changes in focus to reconstruct the three-dimensional image of the cell. Quantitative measurements of fluorescence intensity are further affected by the extent of selecting light from specific planes of the specimen. This latter problem has been solved by using a combination of laser illumination and diaphragms placed in the image plane³⁹.

The local concentration of the fluorescent conjugates also affects the fluorescence intensity measured or visualised in different parts of cells. The distribution of the conjugates can be determined by applying a combination of the controls used for accessible volume and environmental sensitivity.

Nonperturbing indicators of physiological processes

Nonperturbing fluorescent conjugates can be used as indicators of mobility on, within, or between cells. Fluorescence indicators of normal cell-surface mobility have been studied for many years. In an early study Jeon and Bell⁴⁴ used fluorescently labelled antibodies to the cell surface of *Amoeba proteus* and a basic protein derived from a papain preparation to label the cell surface. Results based on a double labelling technique suggested that part of the cell surface could move independently of the lipid portion of the membrane.

In an elegant study, rhodamine-labelled peptides of different sizes have been microinjected into living cells coupled by gap junctions to probe the permeability and exclusion limit of the gap junction channels^{45,46}. Molecules of molecular weight up to 1,200 pass through the channels of *Chironomus* salivary gland cells which indicates that the channels are ~1.0–1.4 nm in diameter. The selectivities of the various channels have been further characterised by varying the total charge of the labelled peptides⁴⁵. For example, several mammalian cell channels can discriminate between 1–3 negative charges on the peptide backbones. The larger electronegativity inhibits passage. In addition, the permeability of multiple components has been directly compared by using mixtures of conjugates prepared with different probes^{45,46}. A control for peptide degradation has also been reported.

Stacey and Allfrey used a similar technique and microinjected a wide variety of rhodamine conjugated proteins into living HeLa cells⁴⁷ to study the process of autophagy (Fig. 1). The segregation of microinjected proteins into autophagic vacuoles exhibited a high degree of selectivity with higher molecular weight proteins turning over faster than low molecular weight proteins. One protein (haemoglobin) never became autophagocytosed. The results with fluorescently conjugated proteins were verified with immunofluorescent and autoradiographic techniques.

More sophisticated applications of nonperturbing fluorescent conjugates involve the use of environmentally sensitive fluorophores and spectral analyses to probe intracellular environments. Fluorescein-labelled ovalbumin has been used to measure the cytoplasmic pH of single cells⁴⁸ based on the observation that the excitation spectra of fluorescein is highly pH dependent⁴⁹. The pH is measured by determining the ratio of fluorescence emission intensity when the cells are excited at two different wavelengths. The effects of local pathlength are normalised since the ratio of intensities is determined. This fluorescence technique of measuring pH is less perturbative and permits better spatial resolution than standard microelectrode methods.

When applying fluorescent conjugates as indicators, the biological effects of the conjugates and the experimental procedures should be carefully examined to make sure that they are actually nonperturbing. The possible degradation of the conjugates inside the cells should also be considered, especially when the conjugates are used as size indicators^{46,47}. This latter problem could be checked more critically in the future by isolating the labelled proteins from the cells after incorporation

Fig. 4 Fluorescence of 5-iodoacetamidofluorescein-labelled actin (a) and lissamine rhodamine B sulphanyl chloride labelled ovalbumin (b) in the same specimen of *C. carolinensis*. Fig. 5 Tetramethylrhodamine isothiocyanate labelled α -actinin incorporated into a living gerbil fibroblast cell. (From Feramisco²⁰.)

by fusion techniques. Furthermore, when spectral characteristics are used as indicators of local environments such as pH, the possible effects of other environmental factors must be ruled out. In all cases, calibration must be performed *in situ*⁴⁸.

Biologically active agents

Biologically active agents which can stimulate, alter or block cell functions include lectins, antibodies, drugs and toxins. These agents are used in probing cell structures and functions. Many of these agents can be fluorescently labelled, permitting detailed investigations on the distribution and mobility of binding sites. The relationship between distribution and biological effects of the labelled agents can also be studied.

The plant lectin, concanavalin A (Con A), has been used as a model ligand in investigations on receptor-ligand complexes⁵⁰⁻⁵⁷. Fluorescently labelled Con A has facilitated studies on the mobility of Con A receptors, the ultimate fate of the ligand and the relationship between receptor mobility and Con A stimulated cellular events⁵¹⁻⁵⁷. It must be emphasised that Con A has many complex effects on cells⁵⁷ and it is difficult to define the complete molecular sequences of events. Similar but more specific experiments have also been performed with antibodies prepared against various cell-surface receptors⁵⁶⁻⁵⁸. These cell-surface associated fluorescent conjugates have been used to measure the mobility of membrane components using several different approaches. The simplest method is the observation of large cells such as muscle fibres⁵⁹ in the fluorescence microscope. Small labelled spots on the cells can be detected when spread over relatively large distances. A second approach involves fusing cells containing different surface fluorescent

conjugates and following the redistribution of the labelled conjugates in the microscope⁶⁰. Poo and colleagues⁶¹ have also studied the accumulation of labelled surface receptors in a uniform electric field applied across the surfaces of cells. Finally, several investigators have used the photobleaching techniques discussed above.

Some drugs can also be fluorescently labelled while maintaining activity. The purpose of labelling the drugs is to study the correlation between the cellular effects and the localisation within the cell. Examples are the tubulin-binding drug colchicine⁶², and the actin-binding cyclic peptides phalloidin¹⁹ and phalloidin⁶³. At the proper concentration, colchicine can cause microtubule depolymerisation and phalloidin and phalloidin can cause actin polymerisation and stabilisation (see ref. 64 for references). Fluorescent conjugates of these drugs have been used to localise pools of tubulin⁶² and F-actin^{19,63} respectively in fixed or extracted cells (Fig. 2). However, it is not yet clear whether these drugs have simply identified pools of tubulin and F-actin or have also altered the normal organisation of the target proteins.

Functional cellular components (molecular cytochemistry)

Molecular cytochemistry¹⁵ has been defined as the re-incorporation of functional cellular components into or onto living cells following purification, fluorescent labelling and assaying function *in vitro*. The experimental protocol is shown in Fig. 3 using actin as a model. The feasibility of molecular cytochemistry has been initially demonstrated using actin labelled with a non-destructive probe, 5-iodoacetamido-fluorescein (IAF). The labelled actin has been proven to be functional in the purified form, in cell-free extracts, and in single-cell models^{13,15-17}. Microinjection of this fluorescent

Fig. 6 Saltatory motion of fluorescent vesicles in 3T3 cells 24 h after incubation with rhodamine-labelled α_2 -macroglobulin. A time lapse video tape recording at a 9:1 time lapse ratio was made of a cell with vigorous intracytoplasmic vesicle saltatory motion. The numbers in the lower right corner of each single frame image represent the real time in seconds after the beginning of the sequence. A phase image is presented at zero time followed by fluorescence images. The asterisk represents an arbitrary non-moving reference point. The inset summarises the motion of this single fluorescent vesicle. (From Willingham and Pastan¹².)

actin analogue into living cells has provided a direct way of visualising actin-containing structures and following the changes in actin distribution during cellular processes such as fertilisation of eggs¹⁷, cytokinesis¹⁷, amoeboid movement^{13,15}, pinocytosis¹³, and Con A capping¹³. Extensive controls *in vitro* and *in vivo* have made the interpretation of the fluorescent images possible^{13,15-17} (Fig. 4). This approach has recently been applied to other cells^{20,21} and other contractile proteins²⁰ (Fig. 5).

The use of fluorescent conjugates specific for receptors in the cell surface has permitted the characterisation of the kinetics of the distribution and the ultimate fate of many ligands. These investigations have included studies on α_2 -macroglobulin^{12,65,66}, epidermal growth factor⁶⁶⁻⁶⁸, insulin⁶⁶⁻⁶⁹, a chemotactic peptide⁷⁰, low-density lipoproteins⁷¹, and acetylcholine receptors⁷¹⁻⁷⁴. All of these fluorescent ligands initially label the cell surface uniformly, but at least some of the ligand-receptor complexes aggregate into patches within a few minutes. Most of the fluorescent conjugates eventually become internalised^{69,75}. The role of internalisation has not yet been defined in detail. The redistribution of some of these ligand-receptor complexes in the plane of the membrane has been quantitated using the fluorescence photobleaching techniques.

Proper use of molecular cytochemistry demands the application of various biological controls in addition to the analysis of physical considerations discussed above. The functional activity of the conjugates must be carefully demonstrated. It requires that: (1) the labelling reaction does not abolish the normal biochemical activity of the substrate, (2) the conjugates have access to the intracellular domains where the function is performed, and (3) the conjugates are not rapidly degraded *in vivo*. The biochemical activities can be readily tested using *in vitro* assays, cell-free extracts or lysed cell models^{13,16}. The use of site-specific probes would provide functionally homogeneous conjugates and would yield unequivocal results with *in vitro* assays¹⁶. The studies with labelled actin have yielded the most definitive biological controls^{13,15-17} to date.

The function inside living cells is much more difficult to assay. For IAF-labelled actin mentioned above, well characterised cellular responses such as cortical wound healing, can be used to test the functionality *in situ*¹³. Furthermore, a comparison of the fluorescent images of biologically active conjugates with non-functional conjugate controls would also indicate the formation of structures related to biological functions^{13,15,17}. Note that the absence of fluorescence from a cellular domain, such as the nucleus^{13,17}, does not necessarily imply that the endogenous component is not present. Negative results could be due to physical exclusion of the conjugate, slow turnover time for the incorporation into specific structures, as well as the absence of a cellular component from a particular region. Therefore, negative results must also be interpreted with caution.

Future prospects

This new approach to cell biology is likely to develop extensively both technically and in its range of biological applications. At the technical level, improvements in the hardware and software applied to intensified image recording and spectral analysis should permit sophisticated manipulations of the experimental data. Measurements of fluorescence polarisation^{14,76,77}, resonance energy transfer^{60,78-80} and fluorescence lifetime could be performed and factors such as accessible volume could be corrected automatically. Detailed molecular information including microviscosity, local polarity, rotational freedom and formation of supramolecular structures could be determined.

The application of this new technique is expected to extend to many different areas of cell biology, through the use of fluorescent conjugates of nonperturbing indicators, biologically active agents and functional cellular components. Components binding specific ions or ligands could be labelled with environmentally sensitive probes and used as indicators of intracellular environments. One such possibility would be the calcium binding protein calmodulin⁸¹. Some drug studies previously relying on radioactive derivatives could be performed with fluorescent

conjugates which would allow the direct observation of uptake, distribution and turnover. Furthermore, the new techniques of blocking cell functions with specific antibodies^{82,83} or modified cellular components⁸⁴ can be combined with the present approaches yielding a more powerful technique. The most dramatic advances will probably be seen in the area of molecular cytochemistry using functional conjugates of proteins, lipids, nucleic acids, carbohydrates and even whole organelles. Careful use of molecular cytochemistry is expected to bring new insights into areas as diverse as cell motility, virus-cell interactions, nuclear-cytoplasmic interactants, cell-cell interactions in tissues, axonal transport, gene expression, and assembly of organelles at both morphological and molecular levels. A direct connection between cell physiology, biochemistry and ultrastructure would then become a reality.

We thank J. Heiple, V. Fowler, B. Luna, L. Tanasugarn, L. Simons, E. Haas and M. Rizzo for helpful discussions, and L. Stryer and J. Yguerabide for reading the manuscript. Valuable collaboration with B. Ware and F. Lanni on fluorescence photobleaching is also acknowledged. Some of the research reported here was supported by NSF grant PCM-7822499 and NIH grant AM 18111.

Variations in the thermal emission of Seyfert galaxies

M. J. Lebofsky & G. H. Rieke

Steward Observatory, University of Arizona, Tucson, Arizona 85721

Accurate monitoring of five Seyfert galaxies demonstrates that they are all variable in the IR region. These fluctuations probably arise when variations in the nonthermal UV sources change the rate of heating of interstellar dust within the nuclei of these galaxies, as demonstrated quantitatively for III Zw 2.

AS soon as the large IR excesses of Seyfert galaxies were discovered, it was recognised that any variability of these excesses could be a vital clue to their nature, in particular as to whether they had a thermal or a nonthermal origin. Despite relatively large measurement uncertainties, early programmes produced evidence that variations do occur^{1–4}. It followed then that greater accuracy would be required to study the variations in any detail, as well as to convince sceptics of the reality of the changes observed. The large change reported recently for 3C120 in the IR⁵ seems to be exceptional, and any general monitoring programme should consider variations of 10–20%.

Recent advances in near IR detector technology make possible routine differential photometry between the brighter Seyfert galaxies and selected nearby stars with an accuracy of 1–2%. This article reports such photometry for III Zw 2, NGC1275, 3C120, NGC4151 and NGC 5548, galaxies selected because of their high degree of variability in the visible. During our observations, all five galaxies varied by many times the measurement errors. Comparison of coordinated IR and visible observations shows that the variations in the two spectral regions are not simultaneous. The behaviour of these galaxies indicates that much of the UV emission of their nuclei is absorbed by interstellar dust and is re-radiated in the IR.

New observations

Our photometry is listed in Tables 1 and 2. Most of the IR measurements were obtained on the Catalina 1.54-m (61-in) telescope, with a field of view 8.5 arc s in diameter and relative to reference areas 10 arc s to the east and west of the nucleus of the galaxy. A few measurements were made on the Steward 2.24-m (90-in), where a beam of 7.8 arc s was used with reference areas 10 arc s to the north and south of the nucleus. No systematic differences are apparent between measurements with the two telescopes.

Two photometers were used, one with a liquid nitrogen cooled InSb detector and one with a liquid helium cooled detector of the same type. Although the filters defining the spectral passbands were identical for the photometers, the lower operating temperature with the second instrument produced slight shifts in filter characteristics. The effects of these shifts

were calibrated and removed from the data by comparing measurements with both photometers in August 1978.

The tabulated errors for the IR photometry reflect only the combined scatter of statistical uncertainties and of a series of comparisons with the local standards on that night. Typically, three or four comparisons were made in each colour. The measurements have been converted to fluxes by tying the local standards in with the network established by Johnson *et al.*⁶ and applying the calibration at $J(1.25 \mu\text{m})$ of 0.0 mag = 1,770 Jy, at $H(1.6 \mu\text{m})$ 0.0 mag = 1,080 Jy, at $K(2.2 \mu\text{m})$ 0.0 mag = 680 Jy, and at $L(3.5 \mu\text{m})$, 0.0 mag = 300 Jy. We believe that the local standards are tied into the primary system with an accuracy of at least 3% (6%, for NGC5548). The absolute calibration is also subject to an uncertainty of 5–10%. Fortunately, for virtually all of our analysis only the uncertainties in the comparisons with the local standards are important.

Photoelectric measurements were obtained with a Johnson *UBVRI* photometer on the Mt Lemmon 1-m (40-in) telescope. The comparison sequences listed by Lyutyi⁷ were used except for III Zw 2, where local standards were determined as part of this programme. As with the IR observations, the tabulated errors refer only to the comparisons with the local standards. The absolute calibration is described by Johnson⁸. The measurements of III Zw 2 on 11 December 1979 were provided by Wieslaw Wisniewski.

Nature of IR variations

Tables 1 and 2 also include an average over the measurements in the J , H , K and L spectral bands for each date, normalised to 1.00 for an arbitrary date and weighted by the tabulated errors. This parameter, plotted in Fig. 1, is convenient for showing the extent of overall variability, although in some cases we have found a strong spectral dependence to the changes (note III Zw 2, discussed below). The same parameter is shown for previous measurements⁵, in the cases of III Zw 2 and 3C120, the parameter is normalised to the data of August 1978, reported in this earlier publication. As is clear from Fig. 1, all five of the galaxies show IR variability at a high degree of confidence.

The five galaxies were selected for this programme on the basis of their large amplitude optical variability. In other

respects, they represent a very broad range of spectral properties and luminosities. As they all varied, we believe that virtually all Seyferts that vary in the visible also vary in the IR.

The simplest explanation for variations in both spectral regions would be that a single, nonthermal source dominates the output of these galaxies from the visible through the IR. However, the variations are not simultaneous between the visible and IR, and in some cases they even occur in the opposite sense in the two spectral regions. This behaviour differs dramatically from that of nonthermal sources such as BL Lac type objects⁹. We therefore will consider models in which different sources dominate the IR and optical spectra.

For these models, the spectra of the nuclei of the galaxies can be divided into four components: (1) a rapidly fluctuating, presumably nonthermal, source that dominates the UV continuum; (2) continuum and line emission by ionised gas, the intensity of which can be expected to vary much more slowly and with smaller amplitude than the UV continuum; (3) the direct output of stars; and (4) the IR excess. Coordinated optical to IR photometry can be combined with spectral photometry to determine the spectra of the UV and IR source components.

Spectra of IR sources

Separation of the UV and IR components of the nuclear source in III Zw 2 should be relatively straightforward, as the nonthermal (optical-UV) continuum is presumably of much higher luminosity than any stellar contribution (the source is sometimes classified as a QSO because of its compact appearance on plates). We assume that the spectra of the continuum components do not change during variations and that the continuum flux at B is entirely from the nonthermal source. The first of these assumptions is suggested by our photometry but needs to be tested by additional observation; a justification for the second follows from our calculations below. With these assumptions, it is possible to estimate the relative contributions of the nonthermal and IR sources at *J*, using the fact that the variation at *J* is intermediate between that at *B* and *K*, and thus that *J* includes contributions from both the nonthermal and the IR sources. A crude estimate would assume that the nonthermal source contributes negligibly to *K*. This estimate can be refined in an iterative way by extrapolating the nonthermal continuum as a power law from *B* and *J* to *K*, determining the variation of the IR source alone at *K*, and repeating the separation at *J*. For 1 May 1979 one finds that the nonthermal fluxes at *J*, *H*, and *K* are respectively 7.3, 8.0 and 9.0 mJy, in reasonably good agreement with a simple extrapolation of the optical-UV continuum¹⁰. The power law fit to the *B* and *J* fluxes has a slope of -0.4 . The IR

source produces fluxes at *J*, *H* and *K* of 2.8, 5.3 and 14.2 mJy, respectively, and a power law fit from *J* to *K* would have an index of ~ -3 .

The very rapid fall in the spectrum of the IR source towards shorter wavelengths was already indicated for several other Seyfert galaxies by spectral inflections near $1 \mu\text{m}$ (ref. 11) and, for NGC1275, 4151, 5548 and 7469, by an approximate separation of the spectrum into stellar, variable UV, and IR components.¹¹ The separation of source components by accurate, coordinated measurements of variability from the UV into the IR should be more reliable than these other two methods. However, for 3C120, NGC1275 and NGC5548 our data are not yet sufficiently extensive for such an analysis. The variability of NGC4151 will be discussed in detail elsewhere.

Role of dust in Seyfert galaxy nuclei

The slope of the spectrum of the IR component in III Zw 2 corresponds to a colour temperature between 1.25 and $2.2 \mu\text{m}$ of 1,500 K, corresponding closely to the maximum temperature at which interstellar grains can survive. If the near IR flux is

Fig. 1 IR Variability of five Seyfert galaxies. Data reported here have been combined with those summarised in ref. 5. The spectrally averaged IR brightness for each galaxy has been normalised to 1.0 near the middle of 1978. The bar at the beginning of 1970 shows the amplitude of a variation of 20% of the normalisation value. When measurement errors exceed the sizes of the symbols, they are indicated with vertical bars. When measurements over an extended period have been combined into a single point, the total period of measurement is shown with a horizontal bar.

radiated by hot, interstellar grains certain limitations can be placed on the size of the emitting region. Assuming the distance is as indicated by a cosmological interpretation of the redshift of $z = 0.089$ with $H_0 = 55 \text{ km s}^{-1} \text{ Mpc}^{-1}$, the radius of a 1,500 K blackbody that can generate the observed near IR fluxes is $\sim 0.2 \text{ pc}$. If the central UV source has a luminosity of $\sim 10^{12} L_\odot$ (see below) and the absorptivity of the grains is neutral between the UV and IR, the grains will reach an equilibrium temperature of 1,500 K at a distance of $\sim 0.2 \text{ pc}$ from the central source. The IR source must be somewhat larger than either of these estimates, as the bright optical and UV flux from III Zw 2 demonstrates that the source is optically thin (at least towards the Earth) and most plausible dust constituents have greater UV than IR absorptivity, raising the equilibrium temperature for a given distance from the central source. However, the dependences on radius are sufficiently steep that the size should be close to the lower limits estimated above: a size of $\sim 0.6 \text{ pc}$ would require an optical depth of only 10% and UV absorptivity 16 times that in the IR. A thermally re-radiating source 0.6 pc in radius would smooth out all variations of the UV flux and delay them with a time constant of $\sim 2 \text{ yr}$. This estimate agrees well with the brightening of III Zw 2 in the IR in September 1979, $\sim 2 \text{ yr}$ after the onset of a powerful optical-UV and radio outburst¹². Further observations in the IR can test this association.

There is already evidence that most Type 2 and those Type 1 Seyfert galaxies with steeply rising IR spectra, such as NGC4151 and NGC5548, emit thermally in the IR¹¹. Among Type 1 Seyfert galaxies, III Zw 2 has one of the most slowly rising spectra into the IR. From its behaviour, re-radiation in the IR by dust is an important component of its spectrum also.

The luminosity of the IR source in III Zw 2 is $\sim 4 \times 10^{11} L_\odot$ (ref. 11). From the strength of $H\alpha^{13}$, the luminosity in the Lyman continuum must be $\sim 2 \times 10^{11} L_\odot$. If the nonthermal continuum can be represented by a power law of index -0.4 from $1 \mu\text{m}$ to the Lyman limit, the luminosity over this spectral range is $\sim 6 \times 10^{11} L_\odot$. Therefore, a significant proportion of the UV continuum of the nonthermal source is absorbed by dust and re-radiated in the IR. The ratio of $H\alpha$ to IR luminosity for III Zw 2 is among the largest for Seyfert galaxies; for most of these

sources the role of dust will be relatively larger than in III Zw 2. From the time scale of the IR variations for all five galaxies we have studied, at least part of this dust lies within 0.1–0.6 pc from the nonthermal sources, depending on the galaxy. The dust therefore lies within or at the outer boundary of the region responsible for the broad emission lines in the Type 1 galaxies.

Conclusions

From accurate monitoring of the near IR fluxes of five Seyfert galaxies, we conclude:

Most or all Seyfert galaxies that vary in the optical-UV also vary in the near IR.

The IR variations are not simultaneous with the optical-UV ones, but have the characteristics of dust reradiating the absorbed nuclear UV continuum.

From the time scale of the IR variability, the dust lies near the gas producing the broad emission lines in Type 1 Seyferts.

The representation of colours in the cerebral cortex

S. Zeki

Department of Anatomy, University College London, Gower St, London WC1E 6BT, UK

New insights into how colour is represented in the cerebral cortex and what variables govern the responses of single cortical colour-coded cells have been gained by the discovery of specific visual cortical areas rich in colour-coded cells.

OUR ability to see an almost infinite variety of colours depends on the presence, in the retina, of only a limited number of receptor types. That the number must be limited was first proposed by Thomas Young. He wrote¹, "Now as it is almost impossible to conceive each sensitive point on the retina to contain an infinite number of particles, each capable of vibrating in perfect unison with every possible undulation, it becomes necessary to suppose the number limited, for instance to the

three principal colours, red, yellow and blue". The identification of three cone pigments in the primate retina^{2–5}, each with a broad response curve, but each having a maximal sensitivity to a different part of the visible spectrum, was a striking confirmation of Young's theory. In its simplest form, this theory supposed that the colour of each 'point' in the field of view is determined by the relative responses of the three cone pigments at a corresponding 'point' in the retina and that this relative response is determined

by the amount of light in each waveband coming from that 'point'. Most colour scientists since Young have, however, assigned a role to more central nervous interactions in accounting for colour perception, and especially for colour constancy^{7,8}. This refers to the persistence of the colour of objects or of surfaces when viewed in lights of different spectral composition, such as daylight and light produced by a tungsten filament bulb. It cannot be explained in terms of energy-wavelength relationships. Other explanations have therefore been sought and, in most, the cerebral cortex has been given a dominant, but neurophysiologically a vague and ill-defined, role. Helmholtz thought learning and judgement to be critical^{6,9}. Hering considered memory to be important¹⁰. Other factors, such as adaptation, have also been suggested⁸. Land^{11,12} in his retinex theory, has sought to explain colour vision (including colour constancy) in computational terms which are essentially independent of energy, surroundings, adaptation, contrast and all psychological factors while being critically dependent on the cortex.

What role, then, does the cortex have in colour perception and how are colours represented there? We decided to explore the responses of single colour-coded cells in the cortex of the rhesus monkey, an animal close to man, with the hope of gaining some insight into these questions.

Wavelength sensitivities of colour-coded cells in the cortex

Anatomical^{13,14} and functional¹⁵⁻¹⁷ studies of rhesus monkey prestriate visual cortex have shown that the different areas within it have remarkably different populations of functional cells, thus leading to the theory of functional specialisation in the visual cortex^{17,18}. One such specialisation occurs in the fourth visual areas which, unlike other prestriate areas, are rich in colour-coded cells¹⁵⁻¹⁹. Since the fourth visual areas are the highest cortical areas to which the analysis of colour has been traced, both anatomically¹⁴ and physiologically^{16,19}, we began by studying the responses and wavelength sensitivities of cells there. Chief among the properties of these areas is the relatively large size of the cells' receptive field^{16,19} (when compared to field sizes at equivalent eccentricities in the striate cortex) and the concentration of field positions in the central 20-30° of the retina. One of the most striking features is the absence of a discernible retinotopic organisation such as that found in the striate cortex²⁰, since field positions in long oblique penetrations move in an unpredictable manner which bears no obvious relation to retinal topography.

Using conventional anatomical and electrophysiological techniques¹⁸, single cells in the fourth visual areas were isolated in the anaesthetised monkey and their receptive fields plotted. Their wavelength response curves (action spectra) were determined by establishing the threshold response at different wavelengths¹⁶. Figure 1 shows some representative narrow-band action spectra. It is evident that cells in V4 can be selective to narrow parts of the visible spectrum. Just how narrow these are is shown in Fig. 2. This is a plot of peak sensitivity against wavelength. Throughout most of the spectrum, bandwidths range from 10 to 50 nm, with many having a bandwidth at half maximum of between 10 and 20 nm. Thus the response of cells in V4 can be said to approximate more closely what may be termed responses to individual colours, or hues, than anything seen in more antecedent parts of the visual system^{21,22}.

One can now go further and ask whether cortical colour representation limits the peak sensitivities of cells to certain parts of the visible spectrum, as in the retina. To rephrase Young¹, "is it necessary to limit the peak sensitivities, for instance to the three principal colours, red, yellow and blue". Figure 3 shows the answer to be no. Between them, the peak sensitivities of these narrow band cells cover almost the entire visible spectrum. Superimposed on this wide distribution, however, is a clustering, most cells having their peak sensitivities at 480 nm (blue), 500 nm (green) and 620 nm (orange-red). Hence these are the regions of the spectrum most strongly represented in the cortex. Purple, an extraspectral colour, is also

strongly represented. Finally, it is noteworthy that, as in the striate cortex²³, no cells have peak sensitivities in the psychophysically least saturated part of the visible spectrum, that is in the 560-570 nm region²⁴, roughly where the long-wave pigment has its maximal absorption. Why this should be so is not clear. With further experiments, cells with peak sensitivities in this region may be found. So far, however, it seems that the cortical representation of this part of the spectrum is poor.

Mapping of colours in the cortex

Given such narrow band cells and given the clustering of peak sensitivities in the blue, green, purple and red, it is interesting to ask how these colours are mapped in the cortex. From micro-mapping experiments, there seems little doubt that cells with particular colour preferences are grouped together in the cortex of V4^{16,19}. This is especially well seen in perpendicular electrode

Fig. 1 Representative action spectra (wavelength selectivities) for some narrow-band cells of the fourth visual areas (V4) of monkey cortex. Action spectra were obtained by using neutral density filters and determining the minimum intensity at every wavelength to which there was a response. The upper two spectra show the responses obtained and the manner of drawing the curves to determine peak sensitivity and bandwidth. Arrows indicate there was no response at the highest intensities available. In the conventional way, curves were drawn through the experimental points by using a family of template curves, all of which were parabolas, and judging by eye which one gave the best fit. Action spectra in discontinuous lines are those of cells inhibited by light of the relevant wavelengths, those in continuous lines represent action spectra of cells excited by the relevant wavelengths.

Fig. 2 A plot of peak sensitivity against bandwidth at half the maximum sensitivity for 63 action spectra obtained from 50 cells. \blacktriangle , Excitation spectra; \circ , inhibitory spectra.

penetrations^{16,19}. In oblique penetrations, the changes in colour preferences of successive cells, with electrode distance, are obvious and, in some, such changes are orderly. A fortunate oblique penetration, one of several, is illustrated in Fig. 4. The electrode travelled a total distance of 1,300 μm . Receptive fields of cells were large, and the shift in receptive field position was apparently random. However, the arrangement of cells with respect to one another was far from random functionally. The first three cells responded with an increase of their maintained discharge to blue, and with a decrease to red light. The next five cells were excited by green and inhibited by purple. These were followed by a cell responding to white light only. Finally, the last two cells were excited by red light and inhibited by blue. Action spectra were plotted for most of the cells. It was found that, throughout this progression, peak excitatory sensitivities were displaced from the short to the long end of the spectrum (except for the jump back from the long to the short part from cell 6 to 7). The peak inhibitory sensitivities, by contrast, were displaced in precisely the opposite direction, going through purple, the complementary, to green. Although the peak opponent sensitivities do not all cross at the white point W on the x-y chromaticity chart (Fig. 4) the order apparent when peak sensitivities are plotted on that chart is impressive and suggests that colours may be mapped in an orderly way in the cerebral cortex. The strong representation given to blue, green, purple and red is also evident in this penetration.

A study of the responses of colour-coded cells in the cortex using Land's retinex experiments

The results given above, as well as previous findings^{16,19}, attest to a high degree of order in the representation of colour in the cerebral cortex: first in generating cells with narrow wavelength selectivities and segregating them into specific cortical areas^{17,18}, then in mapping the retinal surface in these areas in a manner radically different to the retinal map in other prestriate areas¹⁴,

finally in mapping colours in an ordered way. The very segregation of cells sensitive to colour into separate cortical areas suggests that the principles governing the representation of colour in the cortex must be very different from those governing the representation of, say, form or depth. What are these principles?

Edwin Land, the originator of retinex theory, suggested to me that the responses of the cells described above were sufficiently interesting to warrant a new kind of study the purpose of which would be to ascertain the extent to which such responses correspond to, and obey, the rules of colour perception. The simple 'Mondrian' experiments in colour vision²⁵ were designed by Land to answer the classical question of why colours change so little when the wavelength-energy composition of illumination on objects is changed markedly. By using rectangles of arbitrary shape, size, surround and colour, and by choosing matte papers which reflect a constant amount of light in all directions, he created a multicoloured complex image with no recognisable objects. By illuminating this abstract scene with three bands of wavelengths whose relative energies were variable, he brought into focus the fact that colour sensations are essentially independent of energy and also independent of memory, learning, judgement, surroundings and adaptation. These perceptual experiments were so readily adaptable to electrophysiological ones that it seemed interesting to learn whether there were any cortical cells whose responses would correspond to the sensation of colour produced by the rectangles of the Mondrian display. I am much indebted to Land in the execution of the experiments described below.

Provided with this article are three filters, with cutoff points as follows: short wave, 386 and 493 nm (peak transmittance 432 nm); middle wave, 492 and 580 nm (peak transmittance 528 nm); long wave, 592 nm (peak transmittance greater than 660 nm). Each filter was chosen with a bandwidth such that an observer cannot see variegated colours through it. If one were to view a Mondrian display or a similar multicoloured scene through the red filter one would see a pattern which would be the same in disposition for all three sets of cones, even though the energy available to be absorbed by the middle-wave set and short-wave set of cones will be relatively greatly diminished. Thus all the patches which were variously coloured in unfiltered illumination will be seen as a series of light and dark areas against a reddish wash and the area which was red in unfiltered illumination will be seen as one of the lightest. Other areas such as yellow and white will also appear very light and an observer would not find it possible to predict which, among the areas that appear very light, will be red when the display is later viewed in unfiltered light. For the red area, the transition from this high lightness to a deep red in unfiltered illumination can be better understood by examining the Mondrian again, first through the green filter and after that through the blue filter. For either of these filters, as opposed to the red one, the area which is deep red in unfiltered illumination will be very dark. Thus it is as if the

Fig. 3 Histogram of the distribution of peak sensitivities of narrow-band cells in the fourth visual areas (90 spectra obtained from 62 cells).

Fig. 4 Reconstruction of an oblique electrode penetration (ET) through the cortex of V4, made at the level indicated on the surface drawing of the brain. Receptive fields of successive cells are shown to the lower right. As in longer penetrations, shifts in receptive field position bear no obvious relation to retinal topography. The peak sensitivities of the narrow-band cells, determined from their action spectra, are entered on the x - y chromaticity chart to the left. The position of cell 9 (white) on the chart was determined from measurements of the spectral distribution of the light source and the spectral reflection coefficients of the screen. ●, Peak excitatory sensitivity; ○, peak inhibitory sensitivity. Cell 5 was lost before the inhibitory part of the action spectrum could be determined.

deep red of the area in unfiltered illumination is the consequence of the simultaneous presence of the high lightness as seen through the red filter and the two low lightnesses as seen through the green and blue filters. In general three completely independent patterns in terms of lightness and darkness will be seen through the three filters respectively. Each of these patterns as seen through one of the coloured filters will not change if a neutral filter of low, medium or rather high density is superimposed on the colour filter. It is this basic phenomenon which manifests itself as colour constancy when the relative flux in the three illuminators is altered (see below). Are there any colour-coded cells in the cortex whose response is similar to the visual experience produced by viewing Mondrian displays in variable illumination?

If to determine a red region within the field of view as being red it is necessary to illuminate the entire scene, not only by long-wave, but by middle- and short-wave light as well (and hence stimulate all three sets of cones over extended retinal regions), it follows that somewhere along the visual pathways colour-coded cells must give their optimal response when a display containing a red region, say, is illuminated not only by long- but by middle- and short-wave light as well. This was studied in the following way. Once the receptive field and the action spectrum of a cell was plotted, a multicoloured Mondrian display was placed on the screen in such a way that for a cell, say, that responded to blue only, a blue part of the Mondrian covered its receptive field. The Mondrian display was made of special matte papers, selected to have a minimum reflectance higher than 10% for any part of the visible spectrum. The display could be illuminated by three projectors, each equipped with a 750-W tungsten filament bulb and with sharp cut band-pass filters, one passing long, one middle and one short waves. The flux from each projector could be set by a rheostat. The illuminating filters were selected by Land to minimise the diversity of colour sensations from the array of coloured papers when only one projector was turned on and, while satisfying the first condition, to transmit as wide a band of wavelengths and as much light as possible²⁶.

Figure 5 shows the responses of a cell with a narrow action spectrum, responsive to red exclusively. It had no evident opponent input, either in the centre or in the surround. With the

Mondrian display in full illumination, it responded only when the red area was put in its receptive field. However, illuminating the display with long-wave light alone (equivalent to viewing it through the red filter) was totally ineffective in activating the cell. It was also unresponsive to illumination with middle- or short-wave light alone. But when all three lights were switched on simultaneously the cell gave a brisk response. This was the very condition in which the area in the cell's receptive field appeared a vivid red to human observers. Hence one's curious impression that the firing of the cell was in fact the sensation of red. In further experiments, identical responses were obtained for cells responding exclusively to green and to blue.

Table 1 Mondrian areas

Cell	White	Grey	Red	Green	Blue	Magenta	Yellow
'Red' cell	—	—	+	—	—	—	—
'White' cell	+	—	—	—	—	—	—
'Green' cell	—	ND	—	I. + II. +†	—	—	ND
'Red' cell	—	—	+*	—	I. — II. —‡	—	ND

The response of four cells to different areas on the Mondrian display when the energies coming from each area were identical. +, Presence of a response; —, no response. Unless otherwise stated each area of the display was arranged to send 69 milliwatts per steradian per square metre of long-wave light, 31 $\text{mW sr}^{-1} \text{m}^{-2}$ of middle-wave light and 5 $\text{mW sr}^{-1} \text{m}^{-2}$ of short-wave light. ND indicates that the area was not studied for that cell.

* There was only 21 $\text{mW sr}^{-1} \text{m}^{-2}$ of middle-wave and 4 $\text{mW sr}^{-1} \text{m}^{-2}$ of short-wave light at this reading.

† On a second reading for this cell, energies were arranged so that the area sent 120 $\text{mW sr}^{-1} \text{m}^{-2}$ of long-wave, 40 $\text{mW sr}^{-1} \text{m}^{-2}$ of middle-wave and 5 $\text{mW sr}^{-1} \text{m}^{-2}$ of short-wave light. There was a response.

‡ On a second reading, energies were arranged so that there was 15 $\text{mW sr}^{-1} \text{m}^{-2}$ of long-wave, 17 $\text{mW sr}^{-1} \text{m}^{-2}$ of middle-wave and 8 $\text{mW sr}^{-1} \text{m}^{-2}$ of short-wave light coming from that area. The cell did not respond.

While the responses of the cell illustrated in Fig. 5 are impressively clear, the same basic phenomenon was observed in many other cells, even if the responses were often not as sharp. With all such cells, however, the effects of switching off two of the three projectors, leaving only the one of the cell's preferred colour, was always the same; it led to a dramatic fall in the cell's firing rate. Figure 6 A-C shows recordings from groups of cells, all of them responsive to red alone. With the red area of the Mondrian display placed in the receptive field, switching on long wave light alone was ineffective in activating the cells of (A), gave a weak response from those of (B), and a powerful response from those of (C). In the latter, the discharge rate of the cells fell sharply after the initial outburst. Adding the middle- and short-wave lights (which, by themselves, were ineffective in activating the cells) produced the same result for all three groups—a pronounced increase in firing rate. Switching them off also produced the same result—an almost complete cessation of firing.

It is remarkable that for a cell, such as that of Fig. 5, middle- and short-wave lights should, by themselves or in combination, be totally ineffective in activating the cell and yet be instrumental in driving it in the presence of long-wave light—precisely the condition needed for a human observer to experience the sensation of a vivid red in such a multicoloured display. If these cells were themselves comparing the 'lightness records' of that area at the three wavebands, then one might have expected their

Fig. 5 The responses of a narrow-band red-orange sensitive cell (peak sensitivity 620 nm) to the red area of the Mondrian display when the display was illuminated by *a*, long-wave; *b*, middle-wave and *c*, short-wave light. In *d* the response to illuminating the display with all three projectors simultaneously is shown. To provide long-wave light, a Wratten 29 filter was placed in the light patch. The middle- and short-wave projectors had sharp cut band-pass filters with dominant wavelengths at 525 nm and 440 nm respectively.

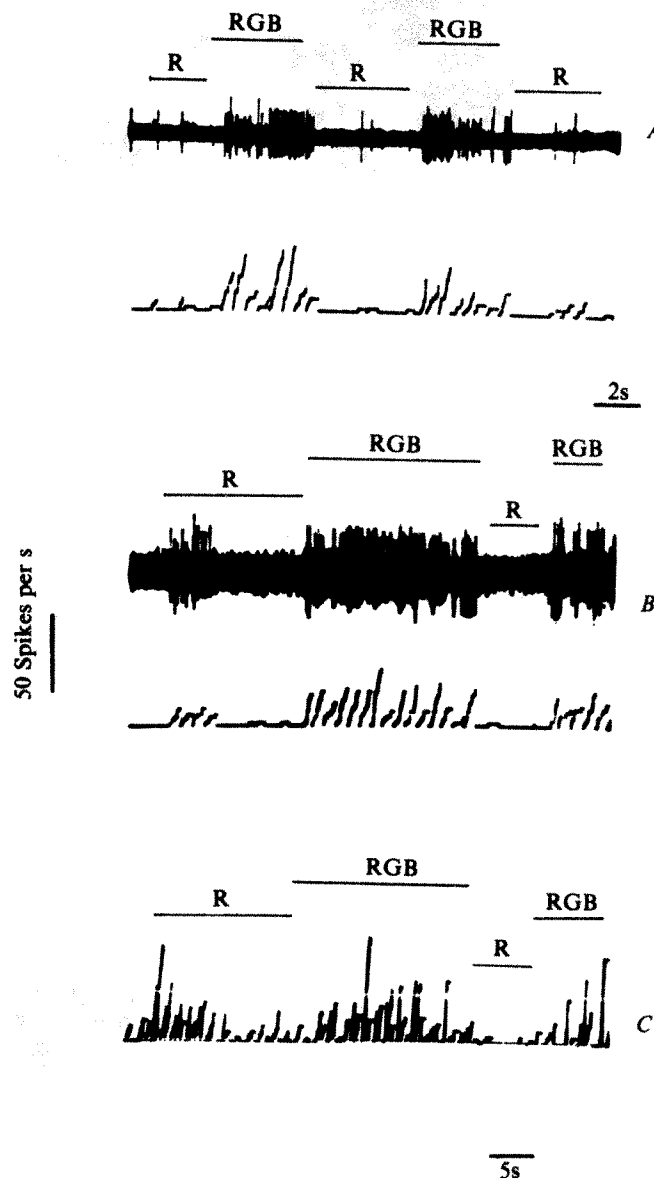

Fig. 6 The responses of three groups (A, B and C) of red-sensitive cells to the red area on the Mondrian display, when the display was illuminated with long-wave light alone (R) and when illuminated with long-, middle- and short-wave light (RGB). In the first two groups, the upper trace is the spike discharge of the cell and the lower trace the frequency of that discharge. For group C only the frequency of discharge is shown.

activity to be influenced in some way by light at each waveband. That the burst of activity occurs only when all three projectors are switched on simultaneously suggests that, if such a comparison is indeed the basis of the response, it must occur at antecedent levels. We have no clear notion whether 'lightnesses' at each waveband are registered by individual cells or whether more subtle interactions, requiring the activity of pools of neurones, is needed. It would therefore be premature to hazard a guess as to what level this might occur at. But V4, with the repetitive representation of each region of the retina in it^{14,16}, is as good a candidate as any. In this context, I emphasise that not all colour-coded cells in V4 behave in this 'experiential' way. Some, with action spectra restricted to the long end of the spectrum, behave much more simply, responding whenever long-wave light is switched on, no matter what part of the Mondrian display is in the receptive field. The role of these cells, and the wiring from them to the ones described above, remain to be established.

If a cell, such as that of Fig. 5, responsive exclusively to the red part of the Mondrian display when the display is trichromatically

illuminated, will nevertheless not respond to it, or do so weakly, when the same display is illuminated by long-wave (red) light alone, it becomes obvious that these responses cannot be dictated by energy-wavelength relationships. But it seemed worth repeating with these cells the experiment that Land reported on human subjects¹². Specifically, how would the cell of Fig. 5, say, respond if the amount of long-, middle- and short-wave light coming from that area on the Mondrian were made identical to the amounts of those lights coming from another part of the Mondrian, say the white, to which the cell was unresponsive. To do this, the amount of long-, middle- and short-wave lights coming off the white area were read off, one by one, using a Gamma Scientific telephotometer fitted with an equal sensitivity filter²⁶. Then, going to the other areas on the Mondrian, the amounts of all three lights were adjusted so that, from each, the identical triplet of energies reached the eye. Table 1 below shows how four narrow band cells on the Mondrian were made to send identical triplets of energy and put in the cells' receptive fields. It is clear that the responses of these cells could be correlated with colour alone and were independent of flux. For the green cell of Table 1, the green area of the Mondrian display was placed in the receptive field and energies adjusted so that three times more long- than middle-wave light reached the eye from it. The area still appeared green to me, a normal trichromat, and the cell gave a good response. Again, for the red cell of Table 1, the blue area was placed in its receptive field and energies adjusted so that while the area still appeared blue, it nevertheless sent twice as much long and middle, than short wave, light to the eye, and yet the cell still did not respond to it. The independence of these responses from flux is striking.

Figure 7 shows an even more remarkable response, that of a cell responding exclusively to white (of which I have encountered a few examples). When energies were made equal so that each area, when placed in the cell's receptive field, was sending an identical triplet of energies, the cell still responded only to the white area.

Fig. 7 The response of a cell selective to white when different areas on the Mondrian display were made to send an identical triplet of energies as that coming from the white area and placed in the cell's receptive field.

Fig. 8 Upper three traces show the response of a cell to illuminating its receptive field diffusely with short-, middle- and long-wave lights separately. The lower trace shows what happens when the red area of the Mondrian display is placed in the cell's receptive field and the entire display illuminated, first with long-wave light alone (R) and then trichromatically (RGB). The energy from the red area when the display was illuminated with long-wave light alone was $540 \text{ mW sr}^{-1} \text{ m}^{-2}$; when trichromatically illuminated it was $560 \text{ mW sr}^{-1} \text{ m}^{-2}$.

Observations such as these imply that for the single cell, just as for perception, the composition of light in terms of energy-wavelength relationships may be of little importance. Cells specifically responsive to flux, either by increasing or decreasing their firing rate, exist in the prestriate cortex (my unpublished results). However, explaining such responses in terms of energy may be wrong, as the behaviour of the cell of Fig. 8 shows. This V4 cell had a high maintained discharge which was abolished by shining short-, middle- or long-wave light diffusely onto the screen facing the animal. Switching the lights, especially the long wave one, off, led to a vigorous discharge. Superficially, then, the cell behaved as if it decreased its firing rate in response to an increase in flux. But its response using the Mondrian display contradicted this first impression. With the red area of the Mondrian display placed in its receptive field, the entire display was flooded with long-wave light (equivalent to viewing the red area of the display through the red filter). Perceptually, the red area now appeared very light, and the cell's maintained discharge was abolished, as expected. Now, adding short- and middle-wave light to the long-wave (equivalent to viewing the red area of the display¹⁵ in full illumination) and thereby increasing the energy further still led, dramatically, to an

increase in firing rate (Fig. 8). Perceptually, the effect of illuminating the Mondrian display with all three lights was to make the red area appear not only a vivid red, but also darker than it had appeared when the display was illuminated by long-wave light alone. In brief, the responses of the cell could be correlated well with human perception and were dramatically illustrated to be independent of flux.

A new neurophysiology of colour vision

The discovery of specific visual areas rich in colour-coded cells has brought us a step closer to understanding the physiology of colour vision and the nature of colour representation in the cortex. It may also provide a new approach to the study of colour vision. First, functional mapping experiments (see Fig. 4) do not reveal a topographically organised 'map' in relation to the retina. Instead they often show a representation of distinct functions (in this instance, colour) with an arrangement of the cells appropriate to that function and not necessarily following any simple topographic relation to the 'visual field'. No doubt the representation of functions also determines the pattern of anatomical connections of these areas^{13,14}. It may therefore be more meaningful to ask for these and other visual areas, how a

function is mapped, rather than how the 'visual field' is mapped.

Second, the responses of the cells reported here correspond so well with the sensation of colour that we can now, perhaps for the first time, apply identical techniques for the study of perceptual responses and those of individual cortical cells. Whereas it may be difficult to equate directly the responses of orientation selective cells with the perception of form, or of depth detecting cells with the perception of distance, there is little difficulty in equating the perception of colour with the response of the individual colour-coded cells described here. It seems timely, therefore, to apply the rules of colour perception in natural situations to the study of single cells, although we are, of course, a long way from knowing whether the cells described here are 'experiential' ones, enabling us to see the many and varied colours around us.

This work was supported by the SRC. I am indebted to Edwin Land for many helpful discussions and for his reading of this manuscript, and to Mathew Alpern for his advice in plotting the action spectra. I also thank J. Z. Young, John McCann and Luca Turin for helpful discussion, Alan Ainsworth for the electrodes, Brenda Crane for the histological assistance, and Bryan Harty for assistance during the experiments.

Transforming activity of DNA of chemically transformed and normal cells

Geoffrey M. Cooper, Sharon Okenquist & Lauren Silverman

Sidney Farber Cancer Institute and Department of Pathology, Harvard Medical School, Boston, Massachusetts 02115

DNA fragments of chemically transformed and normal avian and murine cells induce transformation of NIH 3T3 mouse cells with low efficiencies. High molecular weight DNAs of cells transformed by DNA fragments induce transformation with high efficiencies in secondary transfection assays. It thus seems that endogenous transforming genes of uninfected cells can be activated and efficiently transmitted by transfection. These results are consistent with the hypothesis that normal cells contain genes that are capable of inducing transformation if expressed at abnormal levels.

SUBSTANTIAL evidence indicates that highly oncogenic retroviruses are recombinants between non-transforming viruses and normal cell genes. Examples of transforming viruses that have apparently originated by recombination with different cell genes include avian sarcoma viruses¹⁻³, avian myelocytomatosis virus^{4,5}, avian myeloblastosis virus⁵, avian erythroblastosis virus⁵, Moloney sarcoma virus^{6,7}, Abelson leukaemia virus⁸, Kirsten and Harvey sarcoma viruses⁹ and feline sarcoma viruses¹⁰. In the case of avian sarcoma viruses, it has been demonstrated that genetic information related to the viral transforming gene (*src*) is encoded in the genomes of many vertebrate species³. In addition, uninfected avian and mammalian cells contain a normal cell protein (p60^{src}) that is closely related to the protein encoded by the avian sarcoma virus *src* gene (p60^{src})¹¹⁻¹³. The amount of p60^{src} present in avian

sarcoma virus-transformed cells seems to be at least 100-fold higher than the amount of p60^{src} present in uninfected cells¹¹⁻¹³. These observations suggest that viral transformation may result from overproduction of normal cell proteins as a consequence of the insertion of normal cell genes into a viral genome in a manner permitting their efficient expression. If this is the case, it also seems plausible that the transforming genes of retroviruses represent only a subset of the normal cell genes that are potentially capable of inducing transformation if expressed at higher than normal levels. The present experiments indicate that DNAs of both chemically transformed and normal uninfected cells are capable of inducing transformation on transfection. The results thus provide direct support for the hypothesis that potential transforming genes are encoded in the genomes of normal avian and mammalian cells.

Transformation by sonicated DNA fragments of uninfected cells

The transforming activity of uninfected cell DNAs was assayed by transfection of NIH 3T3 mouse cells. These cells are transformable by direct integration of DNAs of avian sarcoma viruses¹⁴, avian acute leukaemia viruses¹⁵ and murine sarcoma viruses^{7,16}. In addition, NIH 3T3 cells are transformable by subgenomic fragments of murine⁷ and avian¹⁵ sarcoma virus DNAs. The efficiency of transformation by subgenomic fragments of avian sarcoma virus DNA, which contain *src* but apparently lack the normal viral transcriptional promoter, is 100–1,000-fold lower than the efficiency of transformation by intact virus DNA¹⁵. This reduced efficiency is thought to represent the probability of integration of these fragments at a site adjacent to a transcriptionally active promoter in the DNA of the recipient cells. A similar efficiency of transformation by fragments of normal cell DNAs might therefore be expected if transformation could occur by integration of normal cell genes at a site in recipient cell DNA leading to their increased expression.

The donor DNAs used in these experiments were extracted from methylcholanthrene-transformed quail cells (QT-6 cells)¹⁷, methylcholanthrene-transformed BALB 3T3 mouse cells (MC5-5 cells)¹⁸, normal chicken embryo fibroblasts and non-transformed BALB 3T3 and NIH 3T3 mouse cells. Both high molecular weight (MW) and sonicated DNAs were used in transfection assays to investigate the possibility that sonication might increase the transforming activity of uninfected cell DNAs by dissociating potential transforming genes from flanking sequences that might regulate their expression. The MWs of unsonicated DNAs were greater than 20×10^6 whereas those of sonicated DNA fragments were $0.3\text{--}3 \times 10^6$ (Fig. 1). Salmon sperm DNA (MW range $0.3\text{--}20 \times 10^6$, Fig. 1) and sonicated fragments of *Escherichia coli* DNA were included as controls to estimate the frequency of spontaneous transformation of the recipient cells.

DNAs were assayed by transfection of NIH 3T3 cells as previously described¹⁴, except that DNA-treated cells were transferred into soft agarose medium 7 days after transfection and colonies of transformed cells were counted after 2–3 weeks of further incubation. This procedure was found to reduce the background of spontaneous transformation of the recipient cells compared with that observed in assays of focus formation on the

Fig. 1 Molecular weights of DNAs used in transfection assays. DNAs were extracted as described in Table 1 legend and were electrophoresed in 0.8% agarose horizontal slab gels in Tris-acetate buffer, stained with ethidium bromide and photographed under UV light¹⁴. High-MW DNAs of chicken embryo fibroblasts, NIH 3T3 cells and MC5-5 cells were electrophoresed in lanes a–c, respectively. Salmon sperm DNA was electrophoresed in lane d. DNAs of chicken embryo fibroblasts, BALB 3T3 cells and MC5-5 cells were sonicated as described in Table 1 legend and were electrophoresed in lanes e–g, respectively. The MWs of marker fragments of *Hind*III-digested λ DNA (lane h) are indicated ($\times 10^6$).

Table 1 Transformation by uninfected cell DNAs

Donor DNA	Fraction positive cultures		Transformants per μg DNA (total)
	Individual	Total	
Controls			
Salmon sperm (MW $0.3\text{--}20 \times 10^6$)	3/396	3/513	3×10^{-4}
Sonicated <i>E. coli</i> (MW $0.3\text{--}3 \times 10^6$)	0/117		
High MW ($>20 \times 10^6$)			
QT-6	1/48		
MC5-5	0/48		
CEF*	0/46	1/182	3×10^{-4}
NIH 3T3	0/40		
Sonicated fragments (MW $0.3\text{--}3 \times 10^6$)			
QT-6	5/70		
MC5-5	3/48		
CEF*	3/56	16/294	3×10^{-3}
NIH 3T3	3/80		
BALB 3T3	2/40		

High MW DNAs of avian and mammalian cells were extracted essentially as previously described²². Cells were lysed with 0.5% SDS and extracts were deproteinised by digestion with pronase, extraction with phenol and extraction with chloroform-isoamyl alcohol. DNAs were precipitated with ethanol, dissolved in SSC (0.15 M NaCl–0.015 M sodium citrate, pH 7.0), digested with RNase A, re-digested with pronase, extracted with phenol, extracted with chloroform-isoamyl alcohol, precipitated with ethanol and dissolved in SSC. *E. coli* DNA was extracted by the same procedure after lysis of the cells by treatment with lysozyme. Salmon sperm DNA (Sigma) was dissolved in SSC, extracted with phenol, extracted with chloroform-isoamyl alcohol, precipitated with ethanol and dissolved in SSC. Fragments of DNA were prepared by sonication for 10 s using the microtip of a Branson sonifier with an output of 60 W. Recipient cultures of NIH 3T3 cells were transfected with $20 \mu\text{g}$ DNA per culture as previously described¹⁴. DNA-treated cells were transferred into semi-solid medium containing 0.25% agarose¹⁴ 7 days after exposure to DNA. Colonies of transformed cells were counted after 2–3 weeks of further incubation. Data are presented as the fraction of recipient cultures that contained transformed cell colonies (generally 1–5 colonies per positive culture). Each positive culture was considered an independent event for calculation of the transformation frequency.

* CEF DNA was extracted from normal chicken embryo fibroblasts after four to six passages in culture.

original DNA-treated plates. Control experiments indicated that the number of colonies induced by DNA of avian sarcoma virus-infected cells in this assay was similar to the number of foci induced in parallel cultures that were maintained in liquid medium (0.1–1 transforming units per μg DNA).

Results of transfection assays of uninfected cell DNAs are summarised in Table 1. Transfection by high MW DNAs of uninfected cells did not increase the frequency of transformation of recipient cells compared with the background of spontaneous transformation in control cultures exposed to salmon sperm or sonicated *E. coli* DNAs. In contrast, transfection by sonicated fragments of DNAs of both transformed and non-transformed cells resulted in a ~ 10 -fold increase in transformation frequency. The increased transforming activity of sonicated DNA fragments of avian and mammalian cells, compared with salmon sperm and sonicated *E. coli* DNAs, was statistically significant at the $P < 0.001$ level (χ^2 test). The frequency of transformation by sonicated DNA fragments of uninfected avian and mammalian cells was similar to the frequency of transformation by subgenomic DNA fragments of avian sarcoma virus-infected cells¹⁵.

Transformation by high molecular weight DNAs of cells transformed by DNA fragments

Individual colonies of transformed cells were picked and grown to populations of $10^6\text{--}10^9$ cells for further study. These cells had morphologies typical of transformed mouse cells and grew to

high cell densities. Cells transformed by fragments of uninfected cell DNAs did not produce retrovirus particles (assayed by sedimentable DNA polymerase activity of culture fluids¹⁹) or infectious transforming virus. In addition, transforming virus could not be rescued from these cells by superinfection with non-transforming Moloney murine leukaemia virus.

Previous studies indicated that high MW DNAs extracted from nine spontaneous transformants of NIH 3T3 cells did not induce transformation of NIH 3T3 cells in secondary transfection assays (<0.001 transforming units per μg DNA)¹⁴. In contrast, high MW DNAs of cells transformed by subgenomic fragments of avian sarcoma virus DNA induced transformation of NIH 3T3 cells with efficiencies of ~ 0.5 transforming units per μg DNA¹⁵. We therefore assayed the transforming activity of high MW DNAs of NIH 3T3 cells that were transformed by fragments of uninfected cell DNAs to determine whether DNAs of these cells were similarly capable of inducing transformation with high efficiencies.

High MW DNAs of NIH 3T3 cells and of spontaneously transformed NIH 3T3 cells isolated after exposure to salmon sperm DNA did not induce transformation in secondary transfection assays (Table 2). In contrast, high MW DNAs of NIH 3T3 cells transformed by sonicated fragments of DNAs of QT-6 cells, MC5-5 cells, NIH 3T3 cells and normal chicken embryo fibroblasts induced efficient transformation of recipient NIH

Table 2 Transformation by DNAs of NIH 3T3 cells transformed by fragments of uninfected cell DNAs

Donor DNA	Foci per μg DNA	Colonies per μg DNA
Salmon sperm	<0.002	<0.002
NIH 3T3	<0.002	<0.002
NIH (salmon sperm DNA)	<0.005	<0.002
NIH(QT-6 DNA)	0.09	0.3
NIH(MC5-5 DNA)cl 1	0.16	1.5
NIH(MC5-5 DNA)cl 2	0.15	0.3
NIH(MC5-5 DNA)cl 3	0.08	0.2
NIH(NIH DNA)	ND	0.1
NIH(CEF DNA)cl 1	0.03	0.2
NIH(CEF DNA)cl 2	ND	0.8
NIH(CEF DNA)cl 3	ND	1.1

Salmon sperm DNA, high MW DNA of non-transformed NIH 3T3 cells and high MW DNAs of transformed NIH 3T3 cells isolated after exposure to salmon sperm DNA [NIH (salmon sperm DNA)] and to sonicated DNAs of QT-6 cells [NIH(QT-6 DNA)], MC5-5 cells (three independent isolates) [NIH(MC5-5 DNA)cl 1,2,3], NIH 3T3 cells [NIH(NIH DNA)] and normal chicken embryo fibroblasts (three independent isolates) [NIH(CEF DNA)cl 1,2,3] in the experiments described in Table 1 were assayed by transfection of NIH 3T3 cells. Some cultures were maintained under liquid medium and foci of transformed cells were counted 14–17 days after transfection. Other recipient cultures were transferred into soft agarose medium 7 days after transfection and colonies of transformed cells were counted after 2–3 weeks of further incubation. ND, not done.

3T3 cells as assayed by either focus formation or colony formation in soft agarose (Table 2). The morphologies of representative foci of transformed cells are illustrated in Fig. 2. The efficiencies of transformation by DNAs of cells transformed by DNA fragments were ~ 100 -fold higher than the original efficiencies of transformation by sonicated DNA fragments. Thus, NIH 3T3 cells transformed by DNA fragments of uninfected avian and mammalian cells apparently contained transforming genes that were transmitted to new recipient cells by transfection of high MW DNA with relatively high efficiencies.

The transforming activity of restriction endonuclease-digested DNAs of three independent clones of NIH 3T3 cells transformed by fragments of chicken embryo fibroblast DNA was investigated in experiments presented in Table 3. The transforming activity of DNA of NIH(CEF DNA) clone 1 cells was abolished by digestion with *Hind*III but not by digestion with *Eco*RI or *Bam*HI. In contrast, the transforming activities of DNAs of NIH(CEF DNA) clone 2 and clone 3 cells were abolished by digestion with *Bam*HI but not by digestion with *Eco*RI or *Hind*III. These results indicated that transformation in secondary transfection assays was mediated by specific segments of donor DNA. In addition, it seemed that the transforming activity of NIH(CEF DNA) clone 1 cells differed from the transforming activities of NIH(CEF DNA) clone 2 and clone 3 cells, although no conclusion can be drawn concerning the relationship between the transforming activities of NIH(CEF DNA) clone 2 and clone 3 cells.

Endogenous transforming genes of uninfected cells

The findings that DNA fragments of uninfected normal and chemically transformed cells induce transformation with low efficiencies and that high MW DNAs of cells transformed by DNA fragments induce transformation with high efficiencies indicate that endogenous transforming genes of uninfected cells can be activated and efficiently transmitted by transfection. These observations are consistent with the hypothesis that normal cells contain genes that are capable of inducing transformation if expressed at abnormally high levels. A model which accounts for our results in terms of this hypothesis is presented in Fig. 3. The low efficiency of transformation by sonicated DNA fragments of uninfected cells could correspond to the probability of integration of endogenous transforming genes derived

Fig. 2 Morphologies of transformed cells. Representative foci of NIH 3T3 cells transformed by DNAs of NIH(QT-6 DNA) cells (a) and of NIH(CEF DNA)cl 1 cells (b) as described in Table 2 legend were photographed with a magnification of $\times 38$.

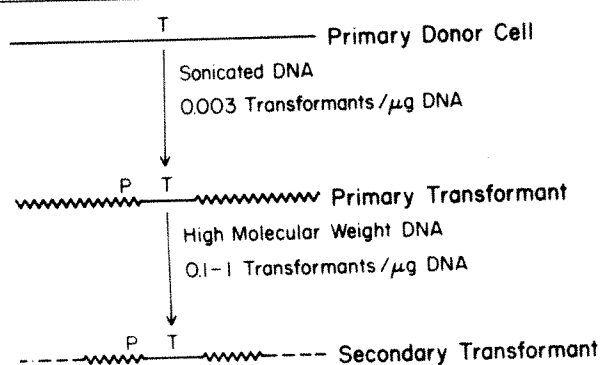

Fig. 3 Model for transfection by endogenous transforming genes. Uninfected cells used as donors of DNA contain genes that are potentially capable of inducing transformation if expressed at abnormally high levels (endogenous transforming genes). Transformation by sonicated DNAs results from integration of endogenous transforming genes (T) in the vicinity of a promoter site (P) in recipient cell DNA, resulting in abnormally high expression of the donor gene. Efficient transformation by high MW DNAs of the primary transformed cells results from transfection of secondary recipient cells by DNAs containing promoter regions (P) derived from the primary recipient genome in tandem with transforming genes (T) derived from the original donor DNA.

from the donor DNA in the vicinity of a transcriptionally active promoter in the recipient cell genome, thereby permitting abnormally high expression of the donor transforming gene. Note that the efficiency of transformation by sonicated fragments of uninfected cell DNAs (3×10^{-3} transformants per μg DNA) is similar to that by subgenomic fragments of avian sarcoma virus-infected cell DNAs ($\sim 1 \times 10^{-2}$ transformants per μg DNA)¹⁵. The transforming activity of sonicated DNA fragments, but not high MW DNAs, may indicate that the biologically active DNA fragments do not include flanking sequences that might regulate the expression of endogenous transforming genes in normal cells. The high efficiency of transformation by high MW DNAs of cells transformed by DNA fragments is consistent with transformation of the secondary recipient cells by DNAs containing promoter regions derived from the primary recipient cell genome in tandem with transforming genes derived from the original DNA fragments. Similar high efficiencies of transformation are observed in transfection assays of DNAs of cells transformed by subgenomic fragments of avian sarcoma virus DNA¹⁵ and by fragments of herpes simplex virus DNA containing the viral thymidine kinase gene²⁰. The transforming activity of avian cell DNAs in NIH 3T3 mouse cells is consistent with the transforming activity of DNAs of avian sarcoma¹⁴ and acute leukaemia¹⁵ viruses in these cells and with the biological activity of the chicken thymidine kinase gene in transfection of Ltk⁻ mouse cells²⁰.

An alternative possibility is that transformation by sonicated DNA fragments results from mutagenic activation of endo-

genous transforming genes of the recipient cells as a consequence of integration of donor DNA fragments into regulatory sequences that normally control expression of these genes. In this case also, the high efficiency of transformation by high MW DNAs of cells transformed by DNA fragments indicates that these cells contain transmissible activated endogenous transforming genes.

We are now investigating the possible relationships between the endogenous transforming genes identified here and the transforming genes of retroviruses. Molecular cloning of the transforming genes of cells transformed by fragments of uninfected cell DNAs should permit studies of these endogenous transforming genes at the molecular level and facilitate investigations of the biological activities of these genes in normal and transformed cells.

Implications for chemical carcinogenesis

The efficiency of transformation by high MW or sonicated DNAs of the two methylcholanthrene-transformed cell lines (QT-6 and MC5-5 cells) used as DNA donors in the present experiments did not differ from the efficiency of transformation by DNAs of non-transformed mouse cell lines (BALB 3T3 and NIH 3T3) or by DNAs of normal chicken embryo fibroblasts. Therefore, it seems that the two chemically transformed cell lines studied did not contain transforming genes that were efficiently transmitted by transfection of high MW DNA. These results suggest that the chemically induced transformation events that resulted in establishment of the QT-6 and MC5-5 cell lines were not transmissible by transfection. Mutational inactivation of a gene encoding a *trans*-acting regulator of the expression of an endogenous transforming gene may be an example of such a transforming lesion. Analysis of the transforming activity of DNAs of a variety of spontaneous and chemically induced neoplasms will be required to determine whether some tumours contain transforming genes that are transmissible with high efficiencies by transfection, as might result from mutational alteration of *cis*-acting regulatory sequences that control expression of endogenous transforming genes.

Since submission of this manuscript, Shih *et al.*²¹ have reported transformation of NIH 3T3 cells by high MW DNAs of 5 out of 15 chemically transformed mouse cell lines.

We thank D. M. Livingston and M. A. Lane for helpful comments on the manuscript. This research was supported by NIH grant CA 18689 from the NCI.

Table 3 Restriction endonuclease digestion of DNAs of transformed NIH 3T3 cells

Donor DNA	Colonies per μg DNA			
	Undigested	EcoRI	HindIII	BamHI
NIH(CEF DNA)cl 1	0.3	0.5	<0.03	0.5
NIH(CEF DNA)cl 2	0.8	0.3	0.3	<0.03
NIH(CEF DNA)cl 3	1.1	0.9	0.5	<0.03

DNAs of three independent clones of NIH 3T3 cells transformed by sonicated fragments of uninfected chicken embryo fibroblast DNA were digested to completion with *EcoRI*, *HindIII* and *BamHI*. The extent of digestion was determined by inclusion of λ DNA in an aliquot of each reaction mixture and analysis of the cleavage products by electrophoresis in agarose gels¹⁴. Transforming activity of undigested and digested DNAs was assayed by transfection of NIH 3T3 cells. Colonies of transformed cells in soft agarose medium were counted as described in Table 2 legend.

Resistance to methotrexate was induced in bone marrow cells of mice by transformation in vitro with DNA from a drug-resistant cell line. Transformed cells were injected in vivo and haematopoietic cells expressing resistance were selected by drug treatment of recipients. Transformed cells had elevated levels of dihydrofolate reductase and demonstrated a proliferative advantage over untransformed cells, indicating successful gene transfer.

THE classic studies of Avery, Macleod and McCarty¹ described alterations of the characteristics of one strain of *Pneumococcus* by the introduction of DNA from a second strain. This formed the basis for the identification of DNA as the primary biological material for storage of genetic information, and demonstrated the feasibility of introducing new genetic information into prokaryotic organisms. Subsequent studies examined the possibility of introducing DNA into mammalian cells. This process of gene insertion is known as transformation. There has been success in a variety of tissue culture systems using a multiplicity of techniques for inserting DNA, for example, viral vectors², cell-cell fusion, fusion to cells of a limited number of chromosomes enveloped in nuclear membranes^{3,4}, and cellular endocytosis of microprecipitates of calcium-DNA complex⁴⁻⁷. Fusion techniques give a relatively high efficiency of information insertion, whereas the calcium precipitation method allows for great selectivity in the introduction of a particular DNA species.

Many mammalian tissue culture cells will take up new DNA. However, the new genetic information must confer some advantage to the cell to demonstrate that they have transformed for a particular characteristic. For example, cell lines lacking thymidine kinase (tk^-) are readily transformed by appropriate DNA to a tk^+ status when grown in the presence of a folic acid inhibitor and thymidine^{6,7}. The presumed mechanism is the integration and functional expression of DNA specifying thymidine kinase by perhaps one cell in 10^6 . This tk^+ cell has a proliferative advantage over tk^- cells when *de novo* DNA synthesis is blocked and the cells are dependent on exogenous thymidine for DNA synthesis and proliferation.

The concept of transferring new genetic information and selecting for its expression using drug-resistance genes and drug

treatment can in principle be applied to intact animals. Certain limitations to such genetic manipulation would seem obvious. The drug used to apply selective pressure must have an acceptable level of toxicity. It must affect the particular tissue being transformed to drug resistance. Finally, if adult animals are used, only tissues demonstrating persistent proliferation throughout life would be amenable to drug-selective pressures. Anti-metabolite drugs used in cancer chemotherapy and blood-forming tissues satisfy these requirements and seem to be ideally suited for such genetic manipulations.

We describe here insertion and selection for genes conferring resistance to methotrexate in bone marrow cells of intact mice. Methotrexate (MTX) is an anti-cancer drug that acts as a folic acid antagonist by inhibiting the enzyme dihydrofolate reductase (DHFR)⁸. Mouse DNA enriched for sequences coding for dihydrofolate reductase was used to transform bone marrow cells *in vitro* and MTX was used as the selective agent *in vivo*. A well studied chromosomal marker was used to distinguish cells transformed to drug resistance from the normal cells of the recipient or from mock-transformed cells introduced as a control.

Strategy of selection of transformed cells

Mouse bone marrow cells with a distinctive chromosomal marker (T6T6)⁹ were obtained from intact animals and treated *in vitro* with a calcium microprecipitate of DNA^{6,7} from a mouse cell line selected for high resistance to MTX and containing reiterated sequences of genes coding for DHFR^{10,11}. The treated marrow, presumed to contain a few stem cells transformed to MTX resistance, was mixed in equal proportions with

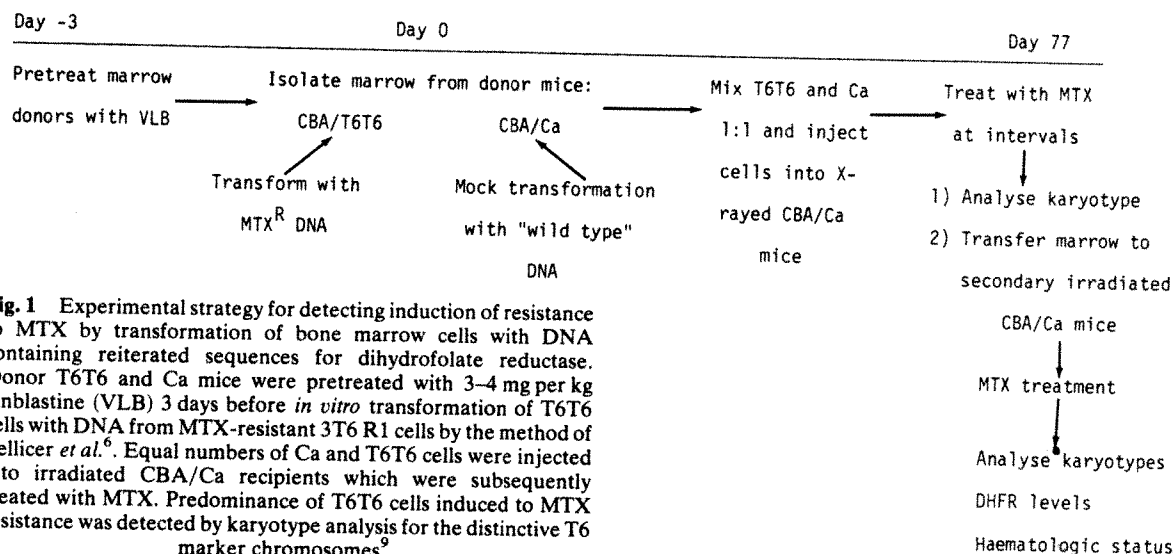

Fig. 1 Experimental strategy for detecting induction of resistance to MTX by transformation of bone marrow cells with DNA containing reiterated sequences for dihydrofolate reductase. Donor T6T6 and Ca mice were pretreated with 3–4 mg per kg vinblastine (VLB) 3 days before *in vitro* transformation of T6T6 cells with DNA from MTX-resistant 3T6 R1 cells by the method of Pellicer *et al.*⁶. Equal numbers of Ca and T6T6 cells were injected into irradiated CBA/Ca recipients which were subsequently treated with MTX. Predominance of T6T6 cells induced to MTX resistance was detected by karyotype analysis for the distinctive T6 marker chromosomes⁹.

Table 1 Karyotype analysis of marrow cells of irradiated CBA/Ca mice receiving a 1:1 mixture of control Ca and transformed T6T6 marrow cells

Recipient*	Duration of MTX treatment (days)	Karyotype (% T6T6)
Primary 1	0-24	57
Primary 2	0-32	59
Secondary 2	32-46	79
Primary 3	0-39	67
Secondary 3a	39-53	97
Secondary 3b	39-67	93
Secondary 3c	39-73	84

*Irradiated CBA/Ca recipients of the 1:1 mixture of Ca cells transformed with wild-type DNA and T6T6 cells transformed with 3T6 R1 DNA were designated 'primary' and each mouse was given a unique number. The day of infusion is designated '0'. Recipients of marrow from 'primary' animals are designated 'secondary' and bear the same identifying number. Karyotype analyses of recipient bone marrow cells were performed after the designated interval of MTX treatment. Between 50 and 100 chromosome spreads were analysed.

Table 2 Karyotype analysis of marrow cells of CBA/Ca mice receiving a 1:1 mixture of control Ca and transformed T6 marrow cells

Recipient*	Period with MTX (days)	Period without MTX (days)	Karyotype (% T6)
Primary 1	0-33	—	79
Primary 2	0-40	—	75
Primary 3	0-47	—	74
Primary 3	0-47	48-68	83
Secondary 3	47-61	—	88, 88, 100†
Primary 4	0-54	—	75

Primary 5	0-65	—	96
Primary 5	0-65	66-113	63

*As in Table 1.

†Three secondary recipients.

syngeneic marrow cells lacking the chromosomal marker (Ca). These cells had been incubated in transforming conditions with control DNA lacking MTX-resistance sequences. The cell mixture was injected into genetically compatible animals that had been irradiated to reduce endogenous haematopoiesis. The infused cells gradually restored blood cell formation in these marrow-depleted recipients. During the period of reconstitution the animals were treated with MTX to produce a relative inhibition of untransformed stem cells and allow for a selective proliferative advantage for those transformed cells which had incorporated a functional gene specifying DHFR. Transformed cells were identified by their distinctive chromosomal marker¹². If there were no selective advantage, then the ratio of marked to unmarked dividing haematopoietic cells would be 50:50 or less because of the contribution of unmarked cells from the irradiated recipient. If, however, there were a proliferative advantage, then marked cells with increased levels of DHFR should be found to constitute more than 50% of the dividing marrow population.

In addition to this indirect means of detecting a population of haematopoietic cells transformed to MTX resistance, we have measured directly the levels of dihydrofolate reductase. Finally, we found that conventional measures of the haematopoietic status of MTX-treated animals provide a convenient measure of the success of the transformation procedure.

The T6 marker was selected because it is easily identifiable (low rate of false positive or negative scoring) and because of the

availability of completely syngeneic animals possessing and lacking this marker. CBA/H-T6T6 mice have the chromosomal anomaly whereas compatible CBA/Ca mice lack the marker.

Bone marrow of mice was selected for transformation by DNA because of its accessibility, high rate of proliferation, and the persistence of pluripotent stem cells throughout adult life. Of all the cell types present in the marrow, only transformation of appropriate stem cells should lead to the establishment of long-term MTX-resistant haematopoietic activity in recipient animals. It is therefore advantageous to choose cell populations rich in stem cells for transformation. Furthermore, transformation may be more efficient in dividing than in stationary cells. For these reasons we attempted to increase the level of proliferating stem cells by pretreating the donor animals with a mitotic inhibitor (vinblastine)¹³ before their use in gene transfer experiments.

MTX was chosen as the selective drug for several reasons: (1) the recent description of mouse cell lines containing highly reiterated gene sequences specifying DHFR, an enzyme conferring resistance to MTX^{10,11}; (2) the titratable suppressive effect of MTX on bone marrow cells; and (3) the potential applicability of the MTX system to human diseases¹⁴.

Haematopoietic effects of MTX treatment in the mouse

We first established a schedule of MTX treatment that would select for drug-resistant haematopoietic cells without lethality in control animals. Groups of normal CBA or C3H mice (18-25 g) were treated using a schedule of 0.5 mg per kg for four doses, 2 mg per kg for four doses and then 4 mg per kg three times weekly. This was not lethal but profoundly affected haematopoiesis. The haematocrit and tibial cellularity were found to be the easiest and most reliable haematological parameters to follow and remained depressed in animals treated continuously with MTX for at least 3 months. No difference in sensitivity to MTX was observed in the mouse strains CBA/Ca and CBA/H-T6T6.

Transformation of mouse bone marrow *in vitro*

The experimental strategy outlined in Fig. 1 was used as a guide for analysing the effectiveness of the transformation procedure.

Highly MTX-resistant mouse fibroblast Swiss 3T6 cells¹⁵ containing reiterated structural genes specifying DHFR were maintained in 4×10^{-4} M MTX and designated 3T6 R1. DNA was isolated from 3T6 R1 and from non-resistant (wild type) mouse cell lines including 3T6 (fibroblastic) and L1210 (lymphocytic leukaemia) and in later experiments from salmon sperm (Sigma). The relative ratio of DHFR synthesis and number of gene copies in 3T6 R1 and 3T6 was ~30:1 (ref. 15).

Table 3 Karyotype analysis of bone marrow and pluripotent stem cells from CBA/Ca mice receiving 1:1 mixture of control Ca and transformed T6T6 bone marrow cells

Recipient	Duration of MTX (days)	Bone marrow karyotype T6T6 (%)	Karyotype of spleen colonies		
			T6T6 (%)	Ca (%)	Mixed (%)
Primary 1	0-24	57	50	50	0
Primary 2	0-40	75	57	26	17
Primary 3	0-47	74	58	8	33

Individual spleen colonies were removed 10 days after inoculation of irradiated recipient with bone marrow cells. A single cell suspension was made from each colony and cells were incubated with colcemid $3 \mu\text{g ml}^{-1}$ for 90 min before treatment with hypotonic KCl and fixation with acetic acid/ethanol for chromosome spreads¹².

Table 4 Karyotype analysis of marrow cells of CBA/T6T6 mice receiving a 1:1 mixture of control T6 cells and transformed Ca marrow cells

Recipient	Expt	MTX treatment	Duration (days)	Karyotype (% Ca)
Primary 1	1	Yes	42	55
Primary 2	1	None	59	33
Primary 3	1	Yes	59	62
Primary 4	1	Yes	71	68
Primary 5	1	None	71	35
Primary 6	1	Yes	97	72
Primary 1	2	Yes	56	67
Primary 2	2	None	56	40

Recipient T6 mice received aliquots of a 1:1 mixture of T6 cells transformed with wild-type DNA and Ca cells transformed with 3T6 R1 DNA. Animals were either untreated or treated with MTX.

DNA co-precipitated with calcium phosphate was used to transform cells by the method of Bachetti and Graham⁴ as modified by Wigler *et al.*⁷.

Equal numbers of CBA/Ca and CBA/H-T6T6 mice were injected intraperitoneally with vinblastine at 3 or 4 mg per kg 3 days before marrow was removed for *in vitro* transformation. The resulting mitotic inhibition is followed by a burst of proliferation¹³. Assays of spleen colony-forming cells (CFU-S) from animals thus treated were relatively depleted of mature cells and enriched ~threefold in pluripotent CFU-S. On the day of transformation (day 0, Fig. 1) single cell suspensions in McCoy's 5A medium with 15% fetal calf serum (FCS) were obtained from femurs and tibias. Cells from Ca and T6T6 animals were placed in separate pools. Cell suspensions of 5×10^6 in 10 ml complete medium (CM) were incubated with 1.0 ml Ca-precipitated DNA containing 40 μ g DNA as described by Wigler *et al.*⁷ for 4 h at 37 °C in 5% CO₂ in tissue culture flasks. T6T6 cells were incubated with 2 or 4 μ g DNA from 3T6 RI MTX-resistant cells, and CBA/Ca marrow cells were incubated with control DNA preparations from MTX-sensitive cells. Thereafter, loosely adherent cells were collected and centrifuged at 150g for 10 min and resuspended in DNA-free CM. After careful cell counts, Ca and T6T6 cells were combined in a ratio of 1:1 and between 5×10^6 and 5×10^7 of the combined cells were injected intravenously into recipient CBA/Ca mice in 0.3–0.4 ml in McCoy's medium with FCS. These recipients had received 850 rad from a cobalt source 24 h previously to eradicate endogenous haematopoiesis. This dose had low lethality but virtually eradicated endogenous CFU-S¹⁶. Between 48 and 96 h after injection, the recipient animals began treatment with the previously established MTX protocol.

Selection of drug-resistant marrow cells

The irradiated mice receiving mixtures of control Ca cells and T6T6 cells transformed with 3T6 R1 DNA were treated with MTX for 24–77 days. Marrow samples were obtained periodically and analysed for karyotype distribution, cellularity and CFU-S content and were injected into secondary irradiated CBA/Ca recipients (Tables 1, 2). Between about days 30 and 40 a clear increase in the percentage of bone marrow cells displaying the T6T6 marker was observed in primary recipient animals. Marrow from these mice was injected into irradiated secondary recipients which were then treated with MTX. They too showed an increased ratio of T6T6 to Ca karyotypes. This same pattern was seen in five independent experiments involving 19 primary recipient animals and 30 secondary recipients. Only two experiments during this same period failed to show a predominance of transformed karyotype.

When MTX treatment of animals receiving transformed marrow cells was stopped, the predominance of T6T6 karyotypes persisted for at least 3 weeks (primary recipient 3, Table

2) but gradually diminished by 8 weeks without treatment (primary recipient 5, Table 2). In later studies the stability of the transformed karyotype in the absence of drug selection was variable (data not shown).

To analyse whether the predominance of T6T6-marked cells involved pluripotent stem cells as well as other proliferating marrow cells, marrow was taken from selected primary recipient animals and 5×10^4 cells were injected into irradiated recipient CBA/Ca mice in a typical CFU-S assay¹⁶. Ten days later the secondary recipients were killed and individual spleen colonies removed for karyotype analysis. As seen in Table 3, the T6T6 karyotype predominated in the pluripotent marrow stem cell population. Mixed T6T6–Ca spleen colonies were also seen, presumably resulting from development of T6T6 colonies on a background of endogenous haematopoiesis in the Ca animals.

Effect of drug administration on cell predominance

We performed control experiments to determine whether T6T6-marked cells had any proliferative advantage or increased resistance to MTX and to analyse the contribution of endogenous haematopoietic repopulation in irradiated CBA/Ca animals. Experimental animals receiving an equal mixture of mock transformed Ca and mock transformed T6T6 and either untreated or treated with MTX for up to 2 months had a predominance of Ca karyotypes anticipated from the contributions of infused Ca cells and endogenous Ca cells (% Ca = 68 ± 12 ; mean \pm 2s.d.).

Finally, in two independent experiments we reversed the usual procedure and transformed Ca cells and used T6 cells as the controls. After injection of a 1:1 mixture of Ca and T6 into irradiated T6 animals they were treated with MTX or left untreated for 2 months. The Ca karyotype predominated only when MTX was administered (Table 4). This gave an unambiguous demonstration that drug therapy determined the predominant marrow population and that the karyotype *per se* did not influence predominance; that is, no inherently greater resistance to MTX was associated with either the CBA/Ca or the CBA/H-T6T6 strain.

Table 5 Haematological status of mice receiving transformed bone marrow

Recipients	MTX treatment (days)	CFU-S (per 5×10^4 cells)	Tibial cellularity (cells per 10^6)	Haematocrit (%)
Controls: saline-treated (15)	None	11.3 (5–15)	8.7 (7.1–10.6)	42 (38–47)
Controls: MTX-treated (15)	21–77	—	3.9 (3.3–4.9)	26 (23–39)
Primary 1	0–33	8.8 (7–9)	13.9	—
Primary 2	0–40	16 (13–19)	9.6	—
Primary 3	0–47	22 (18–25)	6.0	—
Primary 4	0–54	—	9.6	—
Secondary 4	54–72	—	6.6	40
Primary 5	0–65	—	8.2	47

Control animals received no irradiation or bone marrow cells and were injected with saline or MTX as described. Number of animals is indicated in parentheses in column Recipients. Numbers in parentheses in other columns indicate the range of values observed. Primary recipient CBA/Ca mice were irradiated (850 rad) and received a 1:1 mix of control Ca and transformed T6 cells before treatment with MTX for the periods indicated. Secondary recipients were irradiated and received marrow from primary recipients. CFU-S were assayed by injecting 5×10^4 marrow cells into irradiated CBA/Ca recipient mice and counting spleen colonies 10 days later¹⁶.

Haematological status of mice receiving transformed marrow

When it became apparent that cells transformed with MTX-resistant DNA predominated in the marrow of drug-treated recipient animals, simple tests were performed to assess the animals' haematological status. Animals receiving transformed bone marrow and MTX have higher haematocrits and tibial cellularity than control animals receiving MTX but no transforming DNA (Table 5). Furthermore, they have high levels of CFU-S similar to control animals that did not receive radiation or bone marrow cells. Similar results were seen in other independent experiments. Thus, the haematological status of mice receiving transformed bone marrow treated with 3T6 R1 DNA *in vitro* returned toward normal despite persistent treatment with MTX. Autopsies were performed on these animals at intervals up to 150 days after transformation, and sections of visceral organs were taken for microscopic study. No abnormalities were revealed and the animals were clinically well at the time of death.

DHFR assay

To assess whether drug resistance was related to higher enzyme levels in mice receiving transformed bone marrow, spleens were removed from primary, secondary or tertiary recipients of transformed marrow from four independent experiments and assayed for DHFR. These recipient mice were initially treated with MTX and treatment was terminated 5–7 days before collection of tissue for the DHFR assays. Appropriate controls from 12 syngeneic animals, either irradiated or not, and untreated or treated with MTX for periods of up to 6 weeks, were also used as spleen donors. In each case, conditions for control animals were chosen to match those of the experimental group. A radiometric assay for DHFR was performed on sonicated cell-free extracts of spleen^{17,18}. DHFR-specific activity was two- to fourfold greater in the spleen extracts of animals receiving transformed bone marrow than in controls (Table 6). These were considered to be underestimates of the elevations of DHFR in the haematopoietic cells of animals receiving transformed marrow, as the extracts of spleen also included stromal and capsular tissues and non-proliferating lymphoid cells.

Discussion

We have described studies aimed at demonstrating transformation of bone marrow cells to MTX resistance by gene transfer. Extrapolation from tissue culture studies suggests an efficiency of functional gene transfer of 10^{-5} or 10^{-6} for the thymidine kinase gene^{6,7}. Mice receiving 10^7 bone marrow cells receive approximately 10^4 – 10^5 pluripotent stem cells and perhaps several hundredfold greater numbers of committed myeloid and erythroid stem cells. The infusion of an effectively transformed haematopoietic pluripotent stem cell would therefore be expected to be a relatively rare event, occurring in about 1 mouse in 10, yet after 50 or more days of drug selection, animals routinely had elevated levels of the chromosomal marker indicative of cells transformed to drug resistance. Gene insertion into haematopoietic cells may therefore be easier than in some other established cell lines.

As the DHFR genes of our MTX-resistant mouse cell line seem to be similar to those of native mouse DNA, it was not possible to demonstrate unambiguously the introduction of new genes into marrow cells by the Southern blot hybridisation technique¹⁹. Consequently, we undertook a parallel series of identical experiments using the herpes simplex virus thymidine kinase (HSVtk) gene as the transforming agent, rather than DNA derived from a MTX-resistant mouse cell line. With HSVtk DNA used for marrow cell transformation, it has been possible to demonstrate virus-specific gene sequences in mouse spleen cells²⁰. Consequently, several types of drug-resistance genes may be useful in transformation studies in intact animals.

Table 6 Dihydrofolate reductase activity in spleen and karyotype analysis of bone marrow in CBA/Ca recipients receiving 1:1 mixture of control Ca and transformed T6T6 bone marrow cells

Recipient	Duration of MTX (days)	Bone marrow karyotype predominance (%)	DHFR specific activity (% control)
Primary	0–42	49	168
Primary	0–59	62*	375
Secondary	39–67	93	391
Secondary	54–72	83	183
Secondary	65–107	—	208
Tertiary	53–80	—	224

Spleen fragments were sonicated for 30 s in the cold and assayed for DHFR by the method of Hayman *et al.*¹⁸. Results are expressed as the per cent of DHFR in spleens of simultaneously killed control mice.

*This animal received transformed Ca cells and had Ca karyotype predominance. All others received transformed T6T6 cells.

The transfer of genes for drug resistance to haematopoietic cells *in vitro* and their selection in intact animals *in vivo* suggest a variety of clinical applications, for example: (1) the transfer of drug-resistance genes with the objective of enabling patients with cancer to tolerate higher doses of anti-neoplastic drugs; and (2) insertion of drug-resistance genes coupled to other genes to treat human genetic diseases such as the haemoglobinopathies.

Suppression of bone marrow haematopoiesis is one of the main limitations to intensive treatment with most clinical anticancer drugs. If the resistance of marrow cells could be enhanced by simple procedures, then higher doses of drugs could be used to treat cancers of other tissues. This might circumvent dose-limiting marrow-suppressive toxicity and allow better control of a variety of solid tumours. These studies indicate that mice receiving marrow transformed with MTX-resistant DNA tolerate high doses of MTX for long periods of time with nearly normal haematological parameters.

The haemoglobinopathies such as sickle cell disease and thalassaemia seem to be natural targets for treatment by gene transfer techniques. Insertion of a normally regulated and structurally normal β -globin gene should in theory correct the defect in β -thalassaemia major and sickle cell disease. However, as a normal β -globin gene should not itself confer any proliferative advantage to transformed marrow cells, it would be necessary to link it in some way to a gene whose expression is susceptible to selective pressures. Drug-resistance genes are natural candidates for this role.

We thank Dr V. Morhenn for MTX-resistant mouse fibroblast 3T6 cells, and Mrs Debra Morse, Ms Carol Le Févre and Ms Janice Lipeles for technical assistance. This work was supported by USPHS grants CA 15619, GM 18586 and HL 21831. M.J.C. is a recipient of an endowment from the Ambrose and Gladys Bowyer Foundation.

Unequal crossing over in the ribosomal DNA of *Saccharomyces cerevisiae*

Jack W. Szostak* & Ray Wu

Section of Biochemistry, Molecular and Cell Biology, Cornell University, Ithaca, New York 14853

Unequal sister chromatid exchanges occur at the ribosomal DNA locus of yeast during mitotic growth. The frequency of unequal crossing over, as measured by the deletion or duplication of an inserted genetic marker (LEU2), is sufficient to maintain the sequence homogeneity of the rDNA repeat units.

THE ribosomal RNA genes of yeast, *Drosophila*, *Xenopus*, silkworm and sea urchin are arranged in clusters of tandemly arrayed repeating units¹⁻⁸. Yeast rDNA consists of approximately 140 copies of a 9-kilobase repeat unit⁹. Each repeat unit codes for a 5S RNA, and for a 35S precursor RNA which is subsequently degraded to mature 25S, 18S and 5.8S ribosomal RNAs^{1,2,10,11}. Many restriction endonuclease sites have been mapped on the rDNA repeat unit^{1,2,12} and restriction analysis has shown that the repeat units are homogeneous and tandemly arranged. Restriction fragments greater than one repeat unit in length have been cloned^{2,13}.

The histone genes of sea urchin, *Drosophila* and chicken¹⁴⁻¹⁷, as well as other highly repeated sequences and satellite DNAs^{18,19} have also been shown to occur in direct tandem arrays. Repeat units in related strains or species show considerable sequence divergence; yet within any one strain the repeat units are quite homogeneous. Variation between repeat units within one cluster has been detected in *Drosophila* rDNA^{3,4} where some repeat units contain large insertions, and in *Xenopus* where length heterogeneity is due to variation in the copy number of a small internal repeat⁵. No repeat unit heterogeneity has ever been detected in the rDNA of *Saccharomyces cerevisiae*. Thus, sequence variation that is introduced by mutation in individual repeat units must be fixed throughout the entire cluster of repeats. Several mechanisms have been proposed for this process of horizontal evolution or rectification: master slave correction²⁰, democratic gene conversion²¹, saltatory replication²², and unequal crossing over^{23,24}. However, no direct experimental test of these mechanisms has been reported. This is partly due to the difficulty of classical genetic analysis with repeated genes.

We have recently reported the construction of yeast strains with insertions at the rDNA locus²⁵. A plasmid containing yeast rDNA and the *LEU2* gene was made *in vitro* and introduced into yeast by transformation (see Fig. 1). Plasmid integration occurs by homologous recombination; the large amount of homologous rDNA results in preferential integration of the plasmid at the rDNA locus. The transformants thus have a functional copy of the *LEU2* gene in the rDNA cluster which is easily scored in a *leu*⁻ chromosomal background. We have used this marker to detect the deletions and duplications that are generated by unequal crossing over (see Fig. 2). Unequal crossing over occurs during mitotic growth of haploid strains, and causes deletions and duplications of six to eight repeat units. The size of the duplications was measured by restriction enzyme analysis. The relatively small size of the duplications indicates that sister chromatid pairing in the rDNA region is an ordered process. Computer projections from the measured frequency of unequal crossing over show that this process is sufficient to explain the sequence homogeneity of the rDNA repeat units of yeast.

Insertion of *LEU2* and pBR322 at the rDNA locus

The construction of the hybrid plasmid pSZ20 has been described²⁵. The plasmid consists of two fragments of yeast DNA inserted into restriction sites on the *Escherichia coli* plasmid vector pBR322 (ref. 26). The 4.4 kilobase *Bgl*II-B fragment of rDNA is inserted at the *Bam*H-I site of the vector, and serves to direct plasmid integration into the rDNA locus. A 3.5-kilobase *Sall*-*Xho*I fragment containing the intact *LEU2* gene^{25,27,28} is inserted at the *Sall* site of the vector. This fragment complements a non-reverting double mutation in the chromosomal *leu2* gene, and is used for the selection of transformants^{29,30}.

Plasmid pSZ20 DNA transforms yeast with high efficiency and yields unstable transformants. This is apparently due to an origin of DNA replication on the rDNA fragment in pSZ20 (refs 25, 31) which allows autonomous replication⁴² of the free plasmid in yeast. The transformation frequency is high because chromosomal integration is not required for plasmid maintenance; the transformants are unstable due to random segregation of the plasmid molecules during mitosis. Stable integrated-plasmid derivatives are readily obtained by subcloning the initial transformants. The large amount of chromosomal

Fig. 1 Insertion of *LEU2* and pBR322 into the yeast rDNA locus. The circular plasmid pSZ20 was constructed by ligation of restriction fragments of yeast rDNA, the yeast *LEU2* gene, and the *E. coli* vector pBR322 (see ref. 25 for details of construction). The rDNA in the plasmid is a 4.4 kilobase *Bgl*II-B fragment that is approximately half of the rDNA repeat unit. Recombination with chromosomal rDNA homologous to this fragment results in plasmid integration. The integrated structure consists of *LEU2* and pBR322 sequences flanked by a direct duplication of the rDNA *Bgl*II-B fragment. Digestion of this DNA with *Xba*I generates a 9.8 kilobase fragment containing the pBR322 sequences. *Pst*I cuts near one end of the pBR322 DNA, but does not cut rDNA; thus the pBR322 remains attached to long undigested rDNA fragments unless another copy of the insertion is nearby.

* Present address: Division of Genetics, Sidney Farber Cancer Institute, 44 Binney Street, Boston, Massachusetts 02115

rDNA homologous to the plasmid rDNA results in a high rate of plasmid integration. The integrated-plasmid transformants are sufficiently stable through both mitosis and meiosis that the inserted marker can be genetically manipulated by standard methods.

DNA prepared from independent stable transformants was tested for the presence of restriction fragments diagnostic of the site of plasmid integration. Integration of one to four copies of the plasmid occurred at the rDNA locus in all strains tested²⁵, with multiple copies always occurring in tandem arrays. We have never observed free plasmid or plasmid integrated at other loci. Transformants containing a single copy of plasmid were most abundant (about 50%).

Restriction sites on the circular plasmid pSZ20, the chromosomal rDNA, and the integrated structure are shown in Fig. 1. The fragments generated by *Xba*I and *Pst*I are relevant to the subsequent analysis of unequal crossing over. *Xba*I generates a 9.8-kilobase fragment containing pBR322 sequences. This fragment was used for copy number measurements in which the intensity of this band was compared to the intensity of an independent single copy control. The enzyme *Pst*I cuts the plasmid once, near one end of the pBR322 DNA, without cutting rDNA at all. Therefore *Pst*I digestion of a strain with either a single or two widely separated copies of the insertion does not generate a discrete fragment carrying pBR322 DNA; the pBR322 is attached to a long undigested stretch of rDNA. Conversely, if two copies of the insertion are close together, a discrete *Pst*I fragment will be generated which spans the duplication (see Fig. 2).

Deletion of the *LEU2*-pBR322 insertion

An integrated copy of pSZ20 may be thought of as an insertion mutation. Any rectification mechanisms which operate within the rDNA cluster will tend to either eliminate or duplicate this mutation. The only functional copy of the *LEU2* gene in strain T16 is that inserted in the rDNA locus. The rate at which the insertion was spontaneously deleted was measured by a fluctuation test³² as follows. The insertion strain T16 was grown in complete medium (YPD) to stationary phase, diluted, and distributed into the wells of microtitre dishes so that about one-fourth of the wells would contain a cell. The dishes were incubated at 30 °C for 12 h to allow for six to eight generations of growth. The contents of each well were then mixed and plated onto a YPD plate. After growth at 30 °C for 2 days, the plates with colonies were replicated onto synthetic media without leucine, and scored the next day for the presence or absence of *leu*⁻ colonies.

Of 298 YPD plates, 69 (24%) had colonies. Therefore, most of the wells used to inoculate these plates started with one cell. The 67 plates scored had an average of 140 colonies per plate (9,415 total). Nine of these plates had one or more *leu*⁻ colonies, indicating that a deletion event had occurred during growth of the initial cell in the microtitre well. Each of these nine plates represents an independent deletion event. Therefore, nine events occurred during the growth of 9,415 cells, and the frequency of deletion per generation is $9/(9,415 \times 2)$, or approximately 5×10^{-4} per generation.

Deletion of the inserted *LEU2* gene was stimulated approximately 10-fold by UV irradiation to 50% survival. This observation made it much easier to pick well defined sector colonies. For this reason the analysis of unequal crossing over was done first with UV-induced sector colonies, and then repeated with spontaneously arising sectors.

Duplications generated by unequal crossing over

Unequal cross-overs can result in deletion of an insertion from one chromatid and duplication of the insertion in the other (Fig. 2). These sister chromatids are distributed to the two daughter cells after mitosis and result in a sector colony with two copies of the insertion in the *LEU*⁺ side. In contrast, a non-reciprocal

Fig. 2 Unequal crossing over can lead to duplication or deletion of the rDNA insertion. The parental strain (top) carries a single copy of the insertion, represented as a shaded box embedded in a series of tandemly arrayed rDNA repeats. Following mitotic DNA replication, the two sister chromatids pair prior to recombination. Pairing out of register leads to displacement of the two copies of the insertion relative to each other. Recombination between the displaced copies leads to one daughter cell having two copies and one having none. The daughter cells grow up side by side and form a sector colony in which cells derived from the deletion event are *leu*⁻. The event is easily detected by replica plating the colonies to media lacking leucine.

event such as looping-out excision would leave the *LEU*⁺ side of the sector with only one copy of the insertion.

The *leu*⁻ sides of 10 UV-induced sectors and 11 spontaneous sectors were tested for deletion of the insertion by colony hybridisation³⁰ with labelled pBR322 DNA. A strong hybridisation signal was obtained with the original insertion strain; none was detected with any of the *leu*⁻ strains from sector colonies or with the non-transformed parental strain (data not shown). Thus, the sector colonies result from events causing deletion of the inserted *LEU2* gene.

Duplications of the insertion in the *LEU*⁺ side of each sector were detected as follows. DNA was prepared from each strain³³ and digested with the restriction endonuclease *Xba*I to generate an identical fragment carrying the pBR322 DNA from each insertion. The DNA fragments were resolved by agarose gel electrophoresis and transferred to nitrocellulose paper by the filter blotting method³⁴. The filter was hybridised with a labelled probe containing pBR322 sequences for detection of the insertion, and *SUP3* sequences for detection of the *Xba*I *SUP3* fragment. The *SUP3* fragment serves as an independent single copy internal standard. With this method it appeared that four of the UV-induced sectors (S1, 3, 7, 9) and at least six of the spontaneous sectors (S12, 14, 15, 18, 20, 21 and perhaps S16 and 17) had a higher copy number for the insertion than the parental strain. Variation in the efficiency of DNA transfer to the filter made it difficult to obtain quantitative evidence for duplications with this method. This problem was avoided with the qualitative procedure described below.

Digestion of DNA from duplication strains with the restriction enzyme *Pst*I generates a discrete fragment carrying pBR322 sequences. In the absence of a duplication the pBR322 sequences remain attached to the rDNA, which is not digested by *Pst*I and is larger than the shear size of the isolated DNA. The detection of a discrete *Pst*I fragment is therefore strong evidence for a duplication. In addition, the size of this fragment is a measure of the size of the deletions and duplications generated by unequal crossing over. DNA from strains of all the *LEU*⁺

sectors was digested with *Pst*I; the fragments were then separated by electrophoresis through a low percentage agarose gel. In this system large fragments are well resolved and can be measured accurately. The DNA was transferred to nitrocellulose paper as above and hybridised with labelled pBR322 DNA. Hybridisation was detected with fragments of a length equal to the size of the insertion plus an integral number of rDNA repeat units (see Figs 3 and 4). Four of the ten UV-induced sectors (S1, 3, 7, 9) had duplications, ranging from 1 to 4 repeat units in length. Of the seven spontaneous sectors tested, six (S14, 15, 17, 18, 20, 21) had duplications while one did not (S19). The duplications were of 6, 7 or 8 repeat units. The data for the four UV induced and three of the spontaneous duplications are shown in Figs 3 and 4. All of the strains shown to have duplications by this method had an increased copy number of the insertion (data not shown).

The significance of the difference between UV induced and spontaneous duplications is not clear. In all cases the duplications consist of a small number of rDNA repeats (1 to 8) relative to the size of the rDNA cluster (140 repeats). This distribution could not result from a random pairing of the rDNA repeat units, and must therefore reflect an ordered pairing of the sister chromatids prior to recombination. On most of the lanes, faint bands are seen in addition to one major band. This is apparently due to secondary recombination events that result in displacement of the duplicated copies relative to each other. One of the UV-induced sectors has been completely

Fig. 3 Duplications produced by UV-induced unequal crossing over. DNA from the four UV-induced duplication strains was digested with *Pst*I and electrophoresed on an 0.3% agarose gel at 1 V cm^{-1} for 36 h. The molecular weight markers are a mixture of *Sa*II and *Hind*III digested fragments of λ DNA. The DNA fragments were transferred to a nitrocellulose filter and annealed with labelled pBR322 DNA. The size markers were later visualised in a separate hybridisation with labelled λ DNA. The labelled pBR322 DNA hybridised to yeast DNA fragments corresponding in size to one copy of the insertion (12.2 kilobases) plus an integral number of rDNA repeats (8.9 kilobases), as expected for a fragment spanning a duplication. Strains S1, S3 and S10 (lanes 2, 3 and 5) have fragments corresponding to duplications of 1, 2 and 4 rDNA repeat units, respectively. The pattern for S7 (lane 4) is most simply interpreted as due to randomisation by secondary recombination events, with bands that correspond to 0, 1, 2, 3 and 4 repeat unit separations of the duplicated insertion copies. In all cases faint bands are present at these positions.

randomised by such secondary events. Analysis of subclones from this culture showed that in individual cells the two insertion copies were separated by from one to five rDNA repeat units. In addition, some cells again showed randomised patterns (data not shown).

The rate of rDNA rectification

We have measured the frequency of spontaneous deletion of an insertion in the rDNA locus. These deletions are the result of unequal crossing over. Only cross-overs that occur between rDNA copies close to the *LEU2* insertion result in a detectable event. The average displacement during unequal crossing over is seven repeats out of a total cluster length of 140 repeat units, so that only 7/140 of all events are seen. The estimated frequency of deletion is 5×10^{-4} per generation; therefore, the approximate frequency of unequal crossing over within the whole rDNA cluster is 10^{-2} per generation.

Two independent calculations of the rate of rDNA rectification, based on the measured frequency and extent of unequal crossing over, are described below. We have set the initial conditions for these calculations at a 1:1 ratio of two neutral alleles. The effect of successive deletions and duplications is to cause this ratio to drift, so that the probability distribution of the allelic ratio becomes broadened. Eventually, cell lineages accumulate in which one allele or the other has become fixed in the cluster. For the purpose of these calculations, all deletions and duplications were assumed to be of seven repeat units, and to occur in alternation and randomly throughout the cluster.

Ohta³⁵ has presented a simple method for calculating the mean time required for the fixation of a neutral allele in a cluster by the reiterated action of unequal crossing over. In this model the alleles are assumed to be randomly interspersed. The number of cross-over cycles required for fixation is given by

$$t = -\frac{1}{p} [n^2 (1-p) \log_e (1-p)]$$

where p is the initial frequency of the allele in question, n is the number of cross-over units in the cluster, and one cross-over cycle is defined as one deletion event and one duplication event. We let $p = 0.5$ for an initial ratio of 1:1, and $n = 20$, for a cluster of 140 repeats with cross-over of seven repeats. The time required is 280 cross-over cycles. One cycle requires two unequal cross-overs, which occur at frequency of 10^{-2} per generation. Thus the mean time required for cross-over fixation is 5.6×10^4 generations.

We have developed a method which allows us to calculate the probability distribution of the allelic ratio in a population as a function of time (A. Blodgett and J. W. S., unpublished results). We consider the rDNA cluster to consist of 20 cross-over units, with unequal cross-overs involving deletion or duplication of one cluster of seven repeated units (on average) at a time. The probability of every allelic ratio from 20:0 to 0:20 is specified in a linear array. This array is a vector $\mathbf{p}(n)$, describing the probabilities after the n th cross-over cycle. Initially the probability of a 10:10 ratio is 1.0, and all other ratios have a probability of 0. We then calculate a square transition matrix, π , containing the probabilities of change from any one allelic ratio to any other ratio after one cross-over cycle, such that $\mathbf{p}(n+1) = \pi \times \mathbf{p}(n)$, and $\mathbf{p}(n+k) = \pi^k \times \mathbf{p}(n)$. Thus by repeated squaring of the transition matrix, an operation simple to perform on a computer, we can calculate the probability distribution vector after 1, 2, 4, 8, 16... cross-over cycles. From this probability distribution, we can calculate the probability of drift past any particular allelic ratio. The results of these calculations are summarised in Fig. 5. Drift in the allelic ratio to fixation reaches a 50% probability at 240 cross-over cycles, or about 48,000 generations. This is in good agreement with the calculation by Ohta's method. The difference is probably because complete clustering (linkage) of like alleles was assumed in this particular calculation. Drift from the original 1:1 allelic ratio to a 2:1 ratio

Fig. 4 Duplications produced by spontaneous unequal crossing over. The methods are as described in the legend to Fig. 3, with molecular weight markers in lanes 1 and 6. The strains used in this experiment all generate a discrete *Pst*I fragment that contains pBR322 sequences and therefore have a duplication of the insertion. The spontaneous duplication strains S21 and S14 (lanes 4 and 5) have duplications of 7 and 8 rDNA repeat units, respectively, calculated from the size of the *Pst*I fragment. Two subclones of strain S20 (lanes 2 and 3) have a duplication of 6 rDNA repeat units.

has a 50% probability at 5×10^3 generations, and a probability of 0.1 at 1,000 generations.

Discussion

We have recently shown that it is possible to integrate fragments of foreign DNA into the ribosomal RNA genes of yeast by transformation²⁵. Here we have described the use of these insertions for the analysis of unequal crossing over within the rDNA locus. Both rectification and magnification in repeated genes have been explained by unequal sister chromatid exchanges. The effect of a reciprocal unequal exchange is the generation of a deletion in one chromatid and a duplication in the other (Fig. 2). This process can lead to the elimination or fixation of a mutant allele in a cluster of repeats in the absence of selection. The process of cross-over fixation is analogous to the fixation of a neutral allele in a population by genetic drift, and is subject to a similar mathematical treatment. The variables affecting the rate of cross-over fixation by sister chromatid exchanges in a haploid are the frequency of unequal crossing over, the extent of mis-pairing (that is, the size of the deletions and duplications that are generated) and the number of repeat units in the cluster. The time required for the fixation of a neutral allele is proportional to the square of the number of cross-over units in the cluster.

The generation of deletions and duplications by unequal crossing over can also affect the copy number of repeated genes. The behaviour of the *bobbed* locus of *Drosophila*³⁶ has been studied extensively in this respect. This locus corresponds to the nucleolus organiser, the site of the tandemly repeated rDNA genes, and the *bobbed* mutation is due to a deficiency of rDNA. These deletions are unstable and revert to wild type by recombination. Tartof²⁴ has presented evidence that unequal crossing over is responsible for rDNA magnification in *Drosophila*: the

recombinational events occur in mitotic cells; gene reduction (decrease in copy number) occurs as well as copy number increase; and these events do not occur in a ring-X chromosome where the frequency of viable sister chromatid exchanges would be greatly reduced. The existence of a mechanism that is continuously generating small deletions and duplications at the rDNA locus of yeast suggests that there may be considerable variation in the rDNA copy number within a population. The average copy number in a culture is about 140 repeats per haploid genome³⁷. Natural selection alone may be sufficient to maintain the copy number near this average; alternatively some regulatory mechanism could keep the copy number closer to the optimum value.

The unequal crossing-over model of rectification and magnification does not require any new molecular mechanisms. Although sister chromatid exchanges are normally genetically invisible, they were first seen cytologically by Taylor³⁸ in his classical labelling experiments with *Vicia faba* chromosomes. Recently it has been suggested that chromosome labelling reagents such as ³H or bromodeoxyuridine cause DNA damage and induce the observed sister chromatid exchanges (SCEs). However, Yamamoto and Miklos³⁹ have detected SCEs in *Drosophila* in a ring-Y chromosome. Dicentric chromosomes resulting from sister exchanges were observed at a frequency of 0.3% in the absence of any agents which might be expected to induce this process. Unequal crossing over is familiar in *Drosophila* where it was first observed during genetic analysis of the *bar* duplication. The occurrence of unequal sister chromatid exchanges in a repeated gene cluster is therefore not surprising; in contrast, all other models of rectification require new and more complex forms of recombination.

We have measured the size of the duplications generated by unequal crossing over in yeast rDNA. In all of the events that were analysed the two copies of the insertion were relatively close to each other. The non-random distribution of the two copies has two implications. First, duplications caused by looping out of an rDNA circle including the insertion, followed by its reintegration in the sister chromatid, can be only a small fraction of the events. This mechanism would result in the two copies of the insertion being randomly distributed with respect to each other in the rDNA cluster. Second, the rDNA region of the two chromatids must pair in an ordered manner before

Fig. 5 Computer projections of the rectification process in yeast rDNA. The probability of drift from an initial 1:1 ratio of two alleles to a 2:1 ratio or to complete fixation was calculated as a function of time. These calculations were based on measurements of the rate and extent of unequal crossing over as described in the text. We have assumed two neutral alleles, with like alleles linked (clustered), and that deletions and duplications occur alternately, randomly throughout the cluster, and without effect on the growth rate of the cell. Drift in the allelic ratio then occurs by the random action of repeated small deletions and duplications. Drift to fixation reaches a probability of 0.5 by 4.8×10^4 generations. Drift to a 2:1 ratio should be detectable at 10^4 generations, but is unlikely to be seen at 10^3 generations.

recombination. If any rDNA repeat could pair equally well with any other, unequal crossing over would generate very large deletions and duplications that would probably be deleterious to the cell.

The frequency and extent of unequal crossing over are the two parameters required to describe the process of rectification during mitotic growth of haploid yeast. The calculations presented above and in Fig. 5 show that starting from a 1:1 ratio of two alleles in a cluster, the probability of fixation for either allele is 0.5 at 3.7×10^4 generations, and the probability of drift to a 2:1 ratio in either direction is 0.5 at 4.3×10^3 generations. The probability of drift to a 2:1 ratio after 1,000 generations is 0.1. This projection is consistent with the result of the following

experiment. Petes and Botstein⁴¹ have identified a diploid strain of yeast that is heterozygous for a sequence change in the rDNA, detected as a restriction enzyme site variant. They were able to find recombinant spores heterogeneous for their rDNA. Petes (personal communication) cultured subclones of a haploid strain with a 1:1 ratio of two alleles for 1,000 generations. No change in the allelic ratio was observed. Therefore the actual frequency of unequal crossing over cannot greatly exceed the frequency measured with the rDNA insertion.

Evolution of the inclination of Phobos

Anny Cazenave, Anthony Dobrovolskis & Bernard Lago

Groupe de Recherches de Geodesie Spatiale, Centre National d'Etudes Spatiales, 18, Avenue Edouard Belin, 31055 Toulouse Cedex, France

Two mutually exclusive hypotheses concerning the origin of the martian satellites have commonly been proposed: (1) they were formed in the vicinity of Mars, on orbits not very different from their present orbits, or (2) they originated far from Mars and were somehow captured^{1–3}. Hypothesis (1) had been favoured because the satellites' orbits are nearly circular and equatorial. More recent Viking results imply that the satellites are composed of carbonaceous material^{4,5}, suggesting an asteroidal origin. We show here that the satellites have remained close to their laplacian plane throughout their orbital evolution. Thus Phobos and Deimos need not have originated near the martian equator as previously believed³, but could have been captured in Mars' orbital plane instead, and later evolved to their present inclinations. This new result seems to make hypothesis (2) more plausible.

A substantial secular acceleration of Phobos has been observed^{6,7}, presumably caused by tidal dissipation in the interior of Mars. However, this mechanism seems unable to account for a drastic orbital evolution over the age of the Solar System, particularly for Deimos^{3,8}. On the other hand, Lambeck³ has shown that tides raised by Mars in the satellites, especially in Phobos, can lead to substantial changes in both the semi-major

axis and eccentricity. Because of the tidal coupling between these two elements, Phobos may once have had a very large eccentricity (≥ 0.5), permitting its semi-major axis to decrease across the synchronous orbit. Apparently Deimos has always been outside the synchronous orbit for Mars, but in the far distant past both its eccentricity and semi-major axis may also have been great. Lambeck³ concluded that Phobos, and possibly Deimos, may have been captured into an initial nearly parabolic orbit which subsequently evolved to the present orbit. However, as previously pointed out^{3,8}, tidal interactions alone cannot change the satellites' inclinations to the martian equator by more than a few degrees over the age of the Solar System. This leads to a serious objection to the capture hypothesis: if Phobos and Deimos have been affected only by tides, their initial capture orbits must have had nearly the same orientation as the martian equator, which seems improbable.

In fact the apparent small changes in the satellites' inclinations result from neglecting the precession of their orbits and the obliquity of Mars. Laplace^{9,10} has shown that a satellite orbit maintains a nearly constant inclination to its proper (laplacian) plane during a nodal precession period. This plane lies between the equatorial and orbital planes of the primary and shares a common node with them. The inclination I of the laplacian plane to the planet's equator is given by⁷:

$$mJ_2R^2a^{-3} \sin 2I = \frac{1}{2}Ma^2a_M^{-3} \sin (2\theta - 2I) \quad (1)$$

where m is the mass of Mars, J_2 its coefficient of dynamical oblateness, and R its radius; a is the semi-major axis of the satellite's orbit; M is the mass of the sun; a_M is the semi-major axis of the planet's orbit; θ is the planet's obliquity, the angle between its equatorial and orbital planes. Terms of second order in the planet's eccentricity, and of fourth order in the satellite's have been neglected in equation (1).

As the orbits of Phobos and Deimos are evolved backwards, the influence of the Sun on their motions increases while the perturbations due to the oblateness of Mars decrease. At a critical distance of about 13 martian radii¹¹, the laplacian plane switches from near the martian equator to nearer Mars' orbital plane. Because the tidal interaction does not strongly affect the inclinations of the orbits with respect to the laplacian plane, the satellites approach the martian ecliptic as they evolve back beyond the critical distance. When the satellite's eccentricity is included in the definition of the laplacian plane, the critical distance apparently increases to ~ 14 martian radii.

Fig. 1 Variation of the inclination of Phobos' orbit on the equatorial and orbital planes of Mars, versus its semi-major axis. For simplicity, the satellite's eccentricity has been neglected in calculating the laplacian plane.

To study the evolution of the martian satellites backwards in time, we have numerically integrated their semi-major axes, orbital eccentricities, and inclinations with respect to the laplacian plane, and simultaneously expressed their inclinations with respect to the martian equator and orbital plane. We considered both tides in the planet and tides in the satellites, using the tidal expansion of Mignard¹². This method has the capability of expressing the tidal potential relative to any reference frame; in this case, it is applied to the laplacian plane. Because Phobos and Deimos are in synchronous rotation, we have assumed that their spin axes coincide with their orbital poles throughout the orbital evolution. Thus neither tides in the satellites nor precession can alter their inclinations to the laplacian plane. The detailed method of calculation will be presented elsewhere.

The history of the semi-major axis and eccentricity depends on the frequency dependence of the tidal model. Our results are partly similar to those of Lambeck³, indicating that the eccentricity of the martian satellites may have been very high in the past. However, the orbital inclinations on the laplacian plane always remain small. Figure 1 shows the resulting variation in the inclination of Phobos' orbit to the equator and orbit planes of Mars, for a representative calculation.

As the orientation of the laplacian plane depends on the distance from Mars, we see that the orbital inclination to the equator increases beyond the critical point up to about 25°, the average obliquity of Mars¹³. At the same time, the inclination to the orbital plane of Mars falls to $\sim 1^\circ$. A similar result is expected for Deimos, but the time scale of evolution is far longer. This raises the possibility that the orbits of Phobos and Deimos crossed in the past^{3,8}.

Thus our results indicate that the martian satellites originated very close to the martian orbital plane if they ever have been outside the critical distance of Mars. In particular, this conclusion supports the capture hypothesis.

While we have replaced one 'special' plane (the martian equator) with another (the martian orbit), it is plausible that a

conceivable mechanism for capture would favour the ecliptic. In comparison, there is no obvious reason why capture should occur preferentially into the martian equator. On the other hand, the accretion hypothesis supposes that the primordial satellites' orbits lay in the laplacian plane, which depending on the distance from Mars, approaches either the equatorial or orbital plane. However, in the latter case, accretion would have occurred beyond the critical radius, which seems unlikely according to current accretionary models. Thus, while not inconsistent with an *in situ* formation, our results have removed a major difficulty with the hypothesis that Phobos and Deimos are captured asteroids.

Radiogenic melting of primordial comet interiors

Max K. Wallis

Department of Applied Mathematics and Astronomy, University College, Cardiff CF1 1XL, UK

Comets accreted soon after the initial collapse and cooling of the solar nebula, and containing a plausible fraction of ^{26}Al , would have been significantly heated as this radionuclide decayed. Snow-and-dust balls as described by integrals of the heat conduction equation would melt in the centre if larger than 3–6 km radius. A central, low pressure vapour-droplet mixture is described here, which is conceived to be retained within an ice shell, and providing a potentially hospitable environment for elementary life forms. Refreezing after some million years produces a partially-hollow core.

Cooling and condensation of the solar nebula is thought to have occurred very rapidly, <1 Myr after nucleosynthesis of a component of the Solar System material¹. On Whipple's icy-conglomerate theory (for a recent review see ref. 2), comets also condensed at this early stage out of frozen gases mixed with solid material similar to carbonaceous chondrites, including primordial radioactive components. Whipple and Stefanik³ did investigate the probable heating due to radioactive decay, mainly by ^{40}K for they assumed a 20 Myr interval before condensation, so deriving maximum central temperatures of a few tens of Kelvins for 10-km radius icy comets. Sub-surface cometary material would thus have retained its initial pristine state—the examination of such unevolved material being a principal goal of planned cometary missions.

However, present evidence implies significant amounts of the much more effective radionuclide ^{26}Al were present in early Solar System condensates⁴, quite possibly in sufficient abundance to melt the interiors of comets⁵. This element is rather short-lived (half-life 7.4×10^5 yr) and delivered some $2,000 \text{ cal g}^{-1}$ to chondritic meteorites⁴ (assuming all the β^+ and γ -ray energy to go to heat the radio-isotope fraction to be 6×10^{-5} and the relative Al abundance of ref. 6). Comets, if accreting homogeneously out of this material⁶ with a sizeable

proportion of ices (see legend to Fig. 1), would have been subject to a smaller uniform heating rate

$$Se^{-\lambda t} \text{ where } S/\lambda = 2,000\eta \text{ cal g}^{-1} \\ \lambda^{-1} = 3.2 \times 10^{14} \text{ s}, \eta = 0.1-0.5 \quad (1)$$

This rate is $\sim 10^4$ times higher than that from ^{40}K and so on considered earlier³. To bring ice from low temperatures to melting point 90 cal g^{-1} is required and a further 80 cal g^{-1} is necessary to melt it. Thus the heat S/λ may be sufficient to melt the centre of an initial snowball comet if thermal conductivity is low and the mineral fraction is substantial, $\eta > 0.1$.

The thermal conductivity of an ice-dust comet is poorly determined because of its constitution and compactness. To secure analytical solutions I assume as previously^{3,7,8} representative constants for the density and conductivity:

solid ice + dust ($\sim 200 \text{ K}$):

$$k = 7 \times 10^{-3} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}, \rho = 1.0 \text{ g cm}^{-3}$$

loose snow:

$$k = 4 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}, \rho = 0.25 \text{ g cm}^{-3} \quad (2)$$

with specific heat $c = 0.35 \text{ cal}^{-1} \text{ g}^{-1} \text{ K}^{-1}$, appropriate to 200 K ice. While for ice c varies strongly with temperature, for the present purposes it is only significant that k for ice is much higher than for snow.

Consider first a spherical comet of loose snow and mineral grains. The temperature in the case of uniform k is given adequately by the particular integral of the diffusion equation⁹:

$$T = T_0 + \frac{S}{c\lambda} (a \sin ar / r \sin aa - 1) e^{-\lambda t}, \alpha = (\rho c \lambda / k)^{1/2} \quad (3a)$$

$$= T_0 + \frac{S\rho}{6k} \left\{ a^2 - r^2 + a^2 O(\alpha^2 a^2) \right\} e^{-\lambda t} \quad (3b)$$

T_0 is the surface temperature, somewhat higher than the local radiation temperature T_r , which itself is just a few Kelvins far from the Sun in the 'Oort cloud' of comets, but could be some tens of Kelvins if the comets condensed early in the cooling phase of the supernova and solar nebula gases¹. The maximum, steady state value of T_0 given by radiation balance is

$$T_{0,\max} = \{T_r^4 + \rho a S / 3\sigma(1-A)\}^{1/4} \quad (4)$$

which for 10-km snowball with $\eta = 0.4$, albedo $A = 0.2$ and negligible T_r gives $T_{0,\max} = 37 \text{ K}$. Transient terms, dependent on unknown initial conditions, have been omitted from equation (3), as this is applicable for times greater than $\rho c a^2 / \pi^2 k = 7 \times 10^3 \text{ yr} \times (a/1 \text{ km})^2$ and for the source decaying little over a diffusion time $[\alpha a \leq \pi/2]$. The scale distance is $\alpha^{-1} = 4 \text{ km}$, so taking the lowest terms in the expansion (3b) is not too accurate for kilometric comets. The centre of this loose snowball comet could melt were the temperature raised by $\Delta T = 273 \text{ K} - 37 \text{ K} (\eta a / 4 \text{ km})^{1/4}$ that is if

$$\frac{\alpha a}{\sin aa} > 1 + \frac{c\Delta T}{S/\lambda}, \text{ implying } a > 3-6 \text{ km} \quad (5)$$

comparable with that suggested previously⁵.

Could the pressure be high enough— $>6 \text{ mbar}$ of the triple point—to allow liquid H_2O ? The hydrostatic pressure due to self-gravity is marginally adequate: $\frac{2}{3}\pi\rho^2 G(a^2 - r^2) = 9(1 - r^2/a^2) \text{ mbar}$. A degree of cohesion between the snow crystals is also to be expected. For vapour diffusing outwards would recondense in the cooler outer layers. As cracks and interstices fill up with condensates, the interior pressure would rise, fissures may develop allowing some outgassing, but further condensation would reseal them. Thus, initially loose snow would be compacted and consolidated into an icy layer possess-

ing tensile strength, readily able to maintain pressures higher than the 6 mbar .

The relatively highly conductive (and perhaps convective) fluid and ice interior and loose snow exterior is most simply described by a two layer model: the solution corresponding to equation (3) for a shell of radius a surrounding a core of radius b , conductivities k_a, k_b is

$$T = \frac{S\rho}{6k_a} e^{-\lambda t} \frac{a^2 - b^2 + (b^2 - r^2)k_a/k_b}{a^2 - r^2} \quad \begin{matrix} r < b \\ b < r < a \end{matrix} \quad (6)$$

with $T(b) = 273 \text{ K}$ at radius b . For $k_a/k_b \ll 1$ (for example, $1/70$ by equation (2)), the interior temperature is nearly constant (273 K) and the shell temperature is a little less than the previous expression (3b). The latent heat L required in the melting or the sublimation of the ice also modifies the internal temperature: a term expressing the fact that the source has decayed while the latent heat is being delivered can be derived⁹. This term is smaller by the factor $6\lambda L b^2 / S a^2 = 0.25(1 - \eta)b^2 / \eta a^2$ than the main term, and expresses a reduced radius b for the liquid core.

Fig. 1 A snowball comet of around 10-km radius (10^{18} g) during the initial melting phase. The temperature T and vapour pressure $p_s \sim \exp(-2,720 \text{ K}/T)$ (ref. 7) are calculated assuming convection is effective in the central vapour-droplet fluid. Comets are presumed to have accreted at a similar period to chondritic meteorites but have lower ^{26}Al radiodecay heating by a factor $\eta = 0.5-0.1$. For along with the mineral content, they retained volatiles in the form of ices of rather greater or comparable mass². The estimate for η encompasses the value $0.4-0.45$ derived if sufficient O and C to make up solar relative abundances are added to the constituents of carbonaceous chondrites⁶. The parametric values (2) are used in calculating the outer snow layer¹⁵.

The structure of a melting nucleus is certainly more complex than this two-layer model. For one thing, water is much denser (factor 4) than the snow. The gravitational pressure of a few mbar is surely too low to crack open the ice shell. Ice is a good conductor see equation (2) and in melting, readily absorbs heat from the interior fluid so the H_2O vapour pressure is probably not much higher. Could there be a central core of water surrounded by vapour? Surely not, for the gravitational potential in the vapour is flat, so the core would splash against the ice sides and fragment into drops. The central region must therefore be a mixture of one part dust and droplets, three parts vapour. The energies in droplets' dynamic motion and surface tension is of order of the potential difference: for example, typical speeds are $\{\frac{2}{3}\pi\rho Gh^2\}^{1/2} \sim 0.2 \text{ cm s}^{-1}$ if the size h of convective cells is guessed as 10 m . The ice to snow transition is also complex. Under the vapour pressure gradient (Fig. 1) sublimation with diffusion outwards and condensation in cooler outer regions is expected,

just as in snow under sub-zero air temperatures on Earth¹⁰. This means a metamorphosis of the snow into larger ice crystals and enhanced thermal conductivity due to vapour transport:

$$k_{\text{eff}} = k + \zeta \frac{L}{RT} \frac{\partial p_s}{\partial T}$$

Assuming $\zeta = \varepsilon v_{\text{th}}/3$, with $\varepsilon = 1$ mm a typical hole size, the additional conductivity is found to exceed k for snow, equation (2), above 200 K. Thus in the 10-km snowball sketched in Fig. 1, a 1-km thick icy layer with enhanced conductivity is expected, and a further 2 km of metamorphosing snow.

There may be additional chemical heating which counteracts latent heat effects. If there had been little chance for radiative processing and polymerisation of the icy grains¹¹ then states of lower chemical energy would be accessible in the vapour-liquid-mineral dust interior, through catalysed chemical and perhaps biological^{8,12} processes. Supposing Solar System abundance of C and 0.2–0.5 eV per C-atom (compare with Van der Waals forces at 0.2 eV per bond; H₂CO polymerisation at 0.37 eV) the extra heat amounts to 80–200 cal^{−1}. Being released quickly from newly-melted material, it makes the effective latent heat negative and may fully counterbalance the thermal capacity (90 cal g^{−1}). If so, once melting has started, the liquid-vapour core grows very quickly (the chemical time scale) and equation (6) describing a fully-developed core is rapidly obtained ($\lambda t \ll 1$).

As the radioactivity decays, the comet centre gradually refreezes, with an exponential decay time of λ^{-1} . Convection may enhance thermal transport, but anyway the ice-water-vapour interior is relatively highly conducting, so the shell-core solution (6) with $k_a \ll k_b$ is appropriate. Allowance for the latent heat can again be made⁹, but only expresses a slowing down in refreezing. In structural terms, freezing proceeds through deposition of frost and hail on the interior of the ice shell, resulting eventually in a hollow core.

Thus a 10-km snowball comet (10⁶ g) would have developed a large fluid core with a 1-km thick icy shell, while the snow surrounding it underwent extensive processing through sublimation, diffusion and recondensation, before the core refroze (with crystallisation effecting further differentiation) in ~ 1 Myr. The hollow core resulting on refreezing provides an explanation for the splitting of some disintegrating comets into fragments of comparable size^{3,13}. Of those observed over the past 25 yr, comets Wirtanen, Humason, Schwassmann-Wachmann 1¹⁴ and Chiron (if it is a comet) seem big enough to have possessed large fluid cores, although comets such as Encke and Halley may have been bigger before centuries of outgassing. The central fluid core would have provided an excellently-protected environment for elementary biological systems¹², particularly for colonies of bacteria which could survive the refreezing and 4,500 Myr isolation, and be released from comets evaporating and disintegrating on approach to the Sun.

I thank Chandra Wickramasinghe and Mike Edmunds for helpful discussions. I acknowledge support under a UK SRC contract.

A search for ultra high-energy γ -ray bursts from celestial sources

P. N. Bhat, N. V. Gopalakrishnan, S. K. Gupta,
P. V. Ramana Murthy, B. V. Sreekantan & S. C. Tonwar

Tata Institute of Fundamental Research, Homi Bhabha Road,
Bombay-400 005, India

We report here the details of an experiment carried out at mountain altitude, at Ootacamund (2.2 km above sea level), India between March 1977 and March 1979, to detect bursts of high energy ($\sim 5 \times 10^{13}$ eV) γ rays from celestial sources. Not having detected any such bursts, we give 99% confidence level upper limits both to their flux and to the primordial mini-black hole explosion rate in the vicinity of the Solar System.

The apparatus consists of four 20-cm deep liquid scintillation detectors, each 1 m² in area located at the corners of a square of side 11 m. Each scintillator is viewed by a RCA 8575 photomultiplier with the associated electronics set at a threshold of 0.33 of the average pulse height for a vertically penetrating incident cosmic ray muon. The scintillators are, therefore, fully sensitive to single charged particles. Low-energy air showers are selected by a fourfold coincidence of the pulses from the scintillators with a resolving time of 1 μ s. The observed shower rate is 0.55 s^{−1} with a negligible contribution from chance coincidences. The primary energy threshold is difficult to calculate precisely; although we can approximate it at $\sim 5 \times 10^{13}$ eV. We looked for events in which a rapid sequence of air showers occurred with a short time separating them. Specifically all events in which three or more showers occurred with inter-shower time separations of 10 ms or less were selected by the burst detection system discussed in detail elsewhere¹. The event times were recorded to an accuracy of 1 ms in UTC (coordinated universal time) and the inter-shower time separations to an accuracy of 1 μ s. The expected chance event rates of the '3', '4' and '5 or more' type bursts due to just poissonian fluctuations are 1.44, 7.9×10^{-3} and 4.3×10^{-5} per day respectively. Thus while the '3' and '4' type of events are trivial, a '5 or more' type of burst is very significant if recorded in an operation period of a year or two. To discriminate against spurious bursts generated by local phenomena like electrical discharges, a dummy system with electronics identical to that of the burst detection system (except that the photomultipliers were absent) was also operated during the experiment. A signal from any one of the four dummy detectors was used to flag out a possible noise event.

In an effective operation time of 4.78×10^7 s (1.51 yr), no '5 or more' type of burst was observed. The numbers of '3' and '4' type of events observed during the same period are 810 and 4 compared with the expected 797 and 4 events respectively due to chance. The absence of any '5 or more' type of bursts allows us to set an upper limit on the frequency of γ -ray bursts.

The 99% confidence level upper limit to the flux of γ -ray bursts, characterised by at least five γ -ray photons each of energy $\geq 5 \times 10^{13}$ eV arriving within a time interval of 0.1 s, is

$$\frac{4.6}{\pi(30 \text{ m})^2 \times 4.78 \times 10^7 \times 1} = 3.4 \times 10^{-11} \text{ m}^{-2} \text{ s}^{-1} \text{ sr}^{-1}$$

Here we assumed that the collection area is that of a circle with a radius of 30 m and the solid angle, 1 sr.

It is obvious that the same results can be used to set an upper limit to the number of exploding mini-black holes postulated by Hawking^{2–8}. Using the same calculation procedure as Fegan *et al.*⁹, who carried out a similar experiment, we arrive at a 99% confidence limit of 2.7×10^3 mini-black hole explosions pc^{−3} yr^{−1}. This compares favourably with the limit of 6×10^3 pc^{−3} yr^{−1} set by Fegan *et al.* for a threshold energy of

$\sim 10^{14}$ eV. Porter and Weekes¹⁰, using an atmospheric Cerenkov technique, obtained an upper limit for mini-black hole explosion rate of $3 \times 10^4 \text{ pc}^{-3} \text{ yr}^{-1}$ at a threshold of 5×10^{12} eV. According to Page and Hawking⁷ and Carr⁸ who discussed in detail the observable consequences of primordial mini-black holes in the so-called elementary particle model, 10–30% of the rest mass (10^{15} g) of an exploding black-hole will result in the emission of a burst of about 10^{30} photons each of energy $\sim 5 \times 10^{12}$ eV, over a time scale of 0.1 s. The above limits have to be considered in the context of this prediction.

We thank A. R. Apte, J. A. Joshi and S. Ramani for their experimental assistance.

Electrogenerative reduction of nitric oxide

Stanley H. Langer & Kevin T. Pate

Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin 53706

Electrogenerative processes are those in which favourable thermodynamics and kinetic factors are utilised in an electrochemical cell to generate by-product electricity while bringing about a desired reaction. The cell actually functions as a reactor to produce a desired chemical or occasionally to destroy an undesired one. Electrode potentials are generated by reactions at the electrodes; they are frequently different from those of conventional electrosynthesis. Here, we describe an exploratory study of the electrogenerative reduction of nitric oxide to favour ammonia production as well as the effect of electrocatalyst, external load, and other parameters on product distributions.

Nitric oxide can be produced in several ways. One method would be through concentration from a polluting effluent gas stream. Another possibility would be passage of an effluent stream through an electrogenerative cell removing nitric oxide while generating d.c. electricity.

The reduction of nitric oxide has been of special interest from a basic and environmental viewpoint¹, both electrochemical reductions^{2–5} and conventional catalytic hydrogenations^{6–10} having been investigated. For the 'electrogenerative' reduction of nitric oxide, the free electrolyte phase is bounded by porous Teflon-backed, gas-permeable, liquid-impermeable, electrodes which are connected through an external variable resistor in series with an ammeter¹¹. Hydrogen at atmospheric pressure reacts in one electrode compartment, while nitric oxide reacts at the other with protons and electrons from the external circuit to generate current at potentials determined by reactions at each electrode. Details of cell construction for constant gas flow at atmospheric pressure are given elsewhere¹².

Identified overall electrode reactions can be represented by

H^+ transported through the electrolyte

By varying external cell resistance and monitoring the current (conversion rate) of the external circuit, polarisation curves can be obtained as shown in Fig. 1 for cells with platinum and ruthenium cathodes and perchloric acid electrolyte. Gas was fed continuously at both electrodes. The open circuit potential of ~ 0.93 V is reminiscent of that for a hydrogen-oxygen fuel cell and may reflect dissociative adsorption at the cathode to give N_{ads} and surface oxygen^{4,13,14} or possibly is due to the intermediate reaction

HNO intermediates have been postulated to decompose to give nitrous oxide and to be reduced by an alternate route to ammonia⁶ or hydroxylamine^{2–5}.

With some polarisation runs, product analyses were obtained for constant current over several hours. Gas chromatographic (GC) analyses for NO, N_2O and N_2 were done on cathode compartment (volume = 0.78 cm^3) outlet and inlet streams on Porapak Q columns. Ammonia and minor amounts of hydroxylamine accumulating in the electrolyte were measured using standard colorimetric methods^{15,16}. Most material balances on products accounted for generated current within 10% or better.

Some results for platinum and ruthenium cathodes (3.88 cm^2 apparent area) at constant current are shown in Table 1. The platinum black electrode was the commercial, American Cyanamid, Teflon-backed LAA-2 type^{17,18} (9 mg cm^{-2}). The ruthenium black electrode (9 mg cm^{-2}) was an AA-2 (refs 19, 20) type mechanically backed with porous Teflon. Possibilities of employing the electrogenerative cell as a chemical reactor are illustrated by Run 1 with platinum where the majority of the feed is converted to nitrous oxide with little ammonia formation. The effect of nitric oxide flow rate variation at lower potential is illustrated by Runs 3 and 4 on platinum where either ammonia or N_2O can predominate. This can be rationalised by strongly adsorbed nitric oxide^{7–9} displacement of surface intermediates with faster flow rates to give less reduced species and longer surface contact time at slower flows to produce more reduced species. The lower potential further favours ammonia formation. In Run 5, sulphuric acid electrolyte with platinum did not give results significantly different from perchloric acid. Results for NO reduction on ruthenium illustrate electrocatalytic specificity towards ammonia formation. Its unusual adsorptive properties for nitrogen and reduced intermediate species^{7,8,21} diminish the dependence of ammonia formation on flow rate.

§ Based on generated current; analysis of cathode gas streams and electrolyte.

|| Overall feed rate is 4.5 cm³ min⁻¹, mixture contains 1.9% NO, 8.6% O₂ in N₂.¶ Involves substantial O₂ reduction.

* Final NO concentration in product gas stream was less than 100 p.p.m. (limit of GC detectability) after single pass through cell.

** Pt black anode, see text.

Ammonia formation favoured by ruthenium makes electrogenerative reactor use attractive in conjunction with thermal conversion of nitrogen and oxygen to NO (ref. 22) to produce ammonia.

Reductions here take place at generated potentials positive to the hydrogen electrode as compared with the frequent cathodic potentials of conventional electrochemical reductions. With reactants separated in contrast to heterogeneous catalytic reductions, reactant competition for adsorptive sites is minimised, allowing thermodynamic factors to operate across the interface to favour reaction. One consequence is the controlled reaction at mild, room temperature conditions. Possibilities for reacting other nitrogen oxides as well as nitrogen and hydrogen to form ammonia in the electrogenerative mode are suggested by these results. The nitrogen-hydrogen reaction in particular may be favoured through minimisation of adsorptive competition.

The high nitric oxide conversion with platinum cathodes raises the possibility of using electrogenerative reactors as a means for NO_x pollution control at stationary power plants. To pursue this, a cathode feed mix of 1.9% nitric oxide and 8.6% oxygen with nitrogen was used with the cell of previous runs in Run 9, where nitric oxide concentration was reduced to less than 100 p.p.m. (0.01%) in a single pass in the presence of oxygen. The high NO conversion involved NO oxidation to NO₂ in the feed stream as well as electrogenerative reduction of NO₂ and remaining NO to ammonia, combined with current generating oxygen reduction to water. Nevertheless, preferential NO reduction in the presence of oxygen should be noted. With the cell at open circuit, NO concentration was not reduced below 1,100 p.p.m. by O₂ oxidation even further downstream. The reduction in NO concentration with the electrogenerative cell is significant in view of present environmental concern over NO_x pollutants²³. Investigations of straight NO electrogenerative reductions as well as simulated pollutant mixtures are continuing.

We thank the University of Wisconsin, the NSF and Exxon for support as well as Robert Pesselman of the Mill Street Foundation for experimental assistance. Any patent rights are assigned to the Wisconsin Alumni Research Foundation.

Leaching behaviour of rhyolite glass

Suresh N. Karkhanis, G. Michael Bancroft,
William S. Fyfe & James D. Brown

Center for Chemical Physics and Department of Geology, The
University of Western Ontario, London, Ontario, Canada N6A 5B7

Glass has long been recognised as a potentially suitable matrix for diluting and stabilising nuclear waste¹⁻⁵. Most of the glasses which have been studied are borosilicates¹⁻³. One notable exception is the aluminosilicate nepheline syenite glass, used in the pioneering Canadian study⁴ that showed much lower apparent leach rates than for borosilicates^{4,5}. The natural aluminosilicate volcanic glass, rhyolite, has existed in some natural environments for millions of years^{6,7}; and, as Mendel has pointed out¹, it could be adopted as a model against which other glasses could be compared for nuclear waste disposal. We report here results on the hydrothermal leaching and recrystallisation of rhyolite at temperatures up to 300 °C, using not only the classical leach monitors of weight loss and solution analyses, but also modern surface probes such as SEM (scanning electron microscopy), ESCA (electron spectroscopy for chemical analyses) and SIMS (secondary ion mass spectroscopy). These surface techniques are especially valuable for gaining a more complete understanding of hydrothermal reactions of glasses or minerals⁸⁻¹⁰.

The quaternary rhyolite sample from Mono Craters, California, was found to be homogeneous with the following composition (wt %): 4.2% Na₂O; 12.4% Al₂O₃; 76.9% SiO₂; 4.6% K₂O; 0.6% CaO; 0.8% FeO (total 99.5%). Either 0.2 g, 0.5 g or 1.3 g disks were drilled, cut, polished and cleaned ultrasonically in an acetone bath. The disks were placed in stainless steel autoclaves along with either (1) ~10 ml of distilled water (pH ~5.8), or (2) 5 g of crushed granite (composition 71.3% SiO₂; 14.4% Al₂O₃; 2.68% Fe₂O₃; 1.43% MgO; 1.68% CaO, 3.43% Na₂O; 3.95% K₂O; 0.07% MnO; 0.11% P₂O₅; 0.41% TiO₂)¹¹ plus 10 ml of distilled water. The autoclave was sealed with a stainless steel cone, and placed in an electrically heated Nichrome V tube furnace at temperatures of 100, 200, or 300 °C for up to 1 week.

The pH of the solution was recorded after cooling; and the aqueous phase was diluted to 50 ml with ~1% HCl. This solution was analysed for Na and Si using atomic absorption, and the glass disks were examined using the Philips 501 SEM, and ESCA 36 spectrometer, and the Applied Research Laboratories ion microprobe mass analyser at the Metaal Instituut TNO, Apeldoorn, Holland.

Table 1 Weight loss (%) of rhyolite disks after leaching in H₂O and granite plus H₂O*

Test condition	Leach time	T (°C)	% Weight loss
H ₂ O	1 hour	100	≤0.01
	2 hours	100	≤0.01
	6 hours	100	≤0.01
	1 day	100	0.01
	2 days	100	0.01
	3 days	100	0.05
	1 week	100	0.08
	1 day	200	<0.1
	3 days	200	0.9
	1 week	200	0.9
	1 day	300	0.16
	3 days	300	3.5
	1 week	300	7.0
	1 week	100	<0.1
Granite plus H ₂ O	1 day	200	<0.1
	3 days	200	0.63
	1 week	200	0.37
	6 hours	300	2.6
	3 days	300	23.5
	1 week	300	31.8

* The 100 °C experiments in distilled H₂O were performed with disks 1.2 cm in diameter and 0.5-cm thick, having a surface area of 4.1 cm² and weighing ~1.3 g. All other leaching experiments were performed with disks 8 mm in diameter and 2 mm thick having a surface area of 1.5 cm² and weighing ~0.2 g.

The weight losses for the leached rhyolite are given in Table 1. At 100 °C, there was very little weight loss, and the rhyolite leach rate at 100 °C of 3.6×10^{-5} g cm⁻² d⁻¹ (Table 2) was ~3–10 times less than those for borosilicate disks studied earlier^{2,5}. At 200 and 300 °C, there was an appreciable weight loss, and noticeable crystalline material appeared after three days of leaching in experiment (1). In the water-plus-granite experiment there was no noticeable crystalline material formed even after 1 week. The pH of the leachate increased slowly at 100 °C from 5.8 to 7.8, and the Na leached into solution from the 0.5 g sample increased approximately linearly with time at 100 °C (for example 3.1, 6.5 and 35.2 µg Na after 6 h, 1 day and 1 week leaching respectively).

The leach rates based on Na at 100 °C are slightly higher than the weight-loss leach rates (Table 2), indicating some selective leaching of Na. However, at 200 °C, the Na and weight loss leach rates are very similar, indicating congruent dissolution. At 300 °C, the lower Na leach rates indicate some selective reprecipitation of Na (see above). In recent laboratory studies at

Fig. 1 Scanning electron micrographs of rhyolite glass after leaching with distilled water. a, Rhyolite at 200 °C, 3 days; b, rhyolite at 200 °C, 7 days; c, rhyolite + granite at 300 °C for 2 days; d, rhyolite at 300 °C, 3 days.

120 °C, Zielinski¹² has also found that Si, K, and U in rhyolites are leached congruently, but previous work on natural weathered rhyolites (perlites) has usually indicated preferential leaching of sodium^{6,7}. Also, recent work by White and Claassen¹³ on rhyolite leaching at 25 °C, shows diffusion controlled parabolic kinetics, rather than the linear kinetics expected for congruent dissolution^{8,9}. Thus the mechanism of leaching probably changes between 25 °C and our higher temperatures.

From the weight losses at 200 and 300 °C for rhyolite (Table 1), and assuming a first-order dissolution process, an activation energy of ~12 kcal is readily calculated. This is very similar to that reported by Adams¹⁴ for rhyolite leaching below 100 °C, and substantially smaller than for borosilicates.

The scanning electron micrographs of the leached 0.2 g samples showed that at 100 °C no noticeable pitting or etching occurs in either experiments (1) or (2). At 200 °C, rather deep etch pits appear after a few days (Fig. 1a), and a crystalline product begins to cover the disk (Fig. 1b). This same product is produced in greater amounts in the 300 °C runs (Fig. 1d) and has been identified as muscovite by powder X-ray diffraction. The stability of muscovite at these temperatures is not surprising from Meyer and Hemley's laboratory observations¹⁵.

Fig. 2 ESCA surface analyses of the rhyolite disks leached in distilled water at 100 °C. The lines for Na, K and Ca are drawn only for clarity.

In contrast with the formation of large amounts of muscovite in distilled water, the glass disks reacted in the presence of granite (Fig. 1c) showed only a small amount of crystalline product which, based on the morphology of the crystals, appears to be feldspar. There must be a precipitation of aluminosilicates on the crystalline phases of the granite, which may be similar to the well-known amorphous silica reprecipitation¹⁶. This reaction is now under more detailed study. Our results, together with those of McCarthy *et al.*¹⁷, suggest that more work is needed on glass dissolution in the presence of complex rock matrices.

Table 2 Leach rates in g(glass) per cm⁻² per day⁻¹*

	T (°C)	Sample weight (g)	Leach rate	
			Weight loss	Na
Na borosilicates	100		$\geq 9 \times 10^{-5} \dagger$	—
			$3.5 \times 10^{-4} \ddagger$	—
Rhyolite	100	1.3	$3.6 \times 10^{-5} \S$	ND

* All leach rates are based on 1 week data. The Na leach rates were calculated assuming all of the glass constituents leached at the same rate as sodium (congruent dissolution).

† Ref. 5. ‡ Ref. 2. § From Table 1.

The ESCA and SIMS measurements complement the above observations, and show that rhyolite has hitherto unobserved surface leaching properties for a glass. From the areas of the appropriate ESCA peaks (Na KLL Auger, K 2p, Al 2p, Si 2p, Ca 2p and O 1s), the glass surface (≤ 50 Å) is readily analysed¹⁸⁻²⁰. The ESCA surface analyses of the unleached samples in atom. % are in semiquantitative agreement with the bulk probe analysis Bulk (and ESCA) analyses in atom. % are: Na; 2.8 (2.9); K; 2.0 (2.2); Al; 5.0 (7.9); Si; 26.5 (33.2); Ca; 0.2 (0.4); O; 63.3 (53.4). At 100 °C, Na and K are indeed leached preferentially from the surface (Fig. 2), as was indicated by the Na leach rates (Table 2). However, on further leaching, at 100 °C, the Na and K surface concentrations increase and approach the unleached values. Moreover, for all samples leached at 200 and 300 °C (1 hour to 1 week), all elemental surface concentrations are the same (within $\pm 10\%$) of the unleached sample. Congruent dissolution is the major mechanism of leaching in these experiments, as was indicated by the leach rates in Table 2.

Further confirmation of the congruent leaching mechanism comes from the SIMS measurements on unleached samples and samples leached at 100 and 300 °C. The leached samples show very similar concentration profiles to the unleached samples. All samples show very little concentration gradient for any of the elements measured; and in the unleached sample and the sample leached at 300 °C, Na and K are actually slightly enriched at the surface. All other SIMS measurements (ref. 8 and N. S. McIntyre, unpublished data) on other glasses have indicated a sharp decrease in surface alkali content after leaching.

We conclude that rhyolite is much more stable to leaching than are the borosilicates previously studied. Moreover, above 100 °C, the SEM, ESCA and SIMS results give no evidence for a surface depleted layer, as has been shown for many other glasses. Even without this layer, the glass is comparatively stable. Crystallisation of muscovite or clay minerals¹² will serve as useful sorbents for leached ions. More research is needed on such aluminosilicate glasses to understand fully the mechanism of dissolution and to minimise the temperature of formation while retaining their high leach stability.

We thank AECL (Canada) for financial assistance, and G. G. Strathdee, J. Tait, P. Taylor, R. Zielinski and H. Claassen for helpful comments and for preprints.

Winds in the thermosphere of the Northern Polar Cap

R. W. Smith & P. J. Sweeney

Ulster Polytechnic, Jordanstown, Newtonabbey, County Antrim, UK

A preliminary report is presented here of a sequence of measurements of the thermospheric wind in the Northern Polar Cap covering nine complete periods of 24 h. This unique data set covers all local times and a range of magnetic activities with K_p values from 0 to 6⁻. Certain major features of the wind pattern were found to be independent of magnetic activity: night-time winds were steady and approximately antisolar, whereas in the morning and evening sectors the wind weakened and the direction became variable as if the observation point passed through a vortex. On the dayside, the wind was northwestward in quiet conditions but tended towards the antisolar direction with increasing activity. The simplicity of the wind pattern in geomagnetic coordinates and its similarity to the published maps of ion drift strongly suggest that the momentum of the neutral gas is supplied from active ion drag and hence the energy of circulation comes from the magnetospheric electric field.

A ground-based optical Doppler technique was used and the observations were made at Longyearbyen (geographic coordinates 78.2° N, 15.6° E) during January 1979. At that time of the year there is unrelieved darkness for the whole day which permitted the continuous observation of the aurora. Although discrete forms were frequently seen in localised areas of the sky, for the most part, observations were being made on the diffuse background which was of subvisual intensity. Measurements of the oxygen emission at 630 nm in the aurora were used to find the wind velocity at a height of ~230 km. Using a passively stabilised scanning Fabry-Perot interferometer determinations of the horizontal components of the neutral wind were made with a typical error bar of 20 ms⁻¹. The maximum speed frequently occurred between 2100 and 0300 MLT (magnetic local time) and was directed towards the Equator. During these observations, the highest speed observed was 450 m s⁻¹ which

occurred at 2400 h on the 27 January 1979 when the magnetic character figure K_p was 4⁺. On less active periods the wind at 2400 h was smaller; for example, on 21 January 1979, when $K_p = 0$, it was 100 m s⁻¹.

In Fig. 1a, a 24-h plot in geomagnetic coordinates shows the wind vectors at 15-min intervals drawn with their tails on the circle which is the locus of the position of Longyearbyen as the Earth rotates. The predominance of the antisolar wind is evident except for a few hours near 0600 and 1700 h magnetic time when the wind weakens which suggests that there are local vortices in the vicinity. The major region of cross-polar flow seems to lie poleward of 78.2°N during the morning and afternoon periods. The value of the magnetic character figure A_p for this day was 23. The wind pattern for a less active day, 21 January 1979, when A_p was 11, is shown in Fig. 1b. Although the antisolar flow clearly dominates the nightside, it is mixed with a westward component on the dayside. This builds up from early morning, maximising in the afternoon and diminishing in early evening before the onset of the equatorward wind. Such behaviour is more typical of lower geomagnetic activity, and was also observed on the 9, 12, 20 and 22 January when A_p was 15, 10, 12, and 14 respectively. Other examples of the same type as in Fig. 1a were found on 24 and 25 January when A_p was 23 and 34 respectively.

Reports of rocket-borne experiments flown at high latitudes within the Polar Cap¹⁻³ have also shown, for the limited duration of the vapour trail, the existence of the antisolar wind. The occurrence of the westward wind on the dayside is a feature of less active days when one may expect that the auroral oval has

Fig. 1 A 24-h plot in geomagnetic coordinates showing vectors representing the neutral wind in the polar thermosphere during: a, 27 January 1979. b, 21 January 1979. The circle is at a geomagnetic latitude of 73.1°N, traced out by the observing site during the period of observation. The vectors are drawn with their tails on the circle. Scale bar, 100 m s⁻¹ MLT.

Fig. 2 A qualitative view of global winds including the effects of convection electric fields. Figure 13 from Fedder and Banks⁵ redrawn to make a direct comparison with Fig. 1.

contracted and the magnetospheric cusp lies on magnetic field lines to the north of Longyearbyen. In these conditions, the ionosphere above the observatory site is in a region of weak penetration of the magnetospheric electric field and, being in shadow from the solar EUV radiation, has a low ion concentration. The ion momentum source being weakened, the influence of the global scale pressure distribution may have greater significance. Note in this connection, that the geomagnetic and geographic frames of reference at Longyearbyen differ in azimuth by ~45°. In consequence, when the data are presented in geographic coordinates, these daytime winds are within a few degrees of westward. A possible mechanism, not involving ions, would require a large scale pressure gradient with pressure increasing towards the Pole which, combined with the Coriolis effect, would drive a westward wind. However, the 0G06 data on exospheric temperatures showed a broad temperature minimum at the Pole at the winter solstice⁴ which is not consistent with the present interpretation.

The general features of a high latitude neutral wind pattern dominated by ion convection are shown in Fig. 2 as given by Fedder and Banks⁵ and are also shown by the present results. The cross-polar antisolar flow arises from the dusk to dawn magnetospheric electric field. Vortices in the morning and evening occur where the sunward convection in the auroral zone causes the neutral wind to reverse direction as latitude decreases. Some workers conclude that winds at high latitudes up to the auroral zone are very much dependent on pressure gradients arising due to Joule heating⁶. However, the major features of the thermospheric wind in the Polar Cap seem to be consistent with the theory that most of the momentum is derived directly from the convecting ions⁷ which transfer energy stored in the magnetospheric electric field into kinetic energy of circulation by active Hall drag. The results presented here show that more energy is transferred with increasing magnetic activity and indicate that a greater latitudinal extent of the thermosphere is included in the circulation with greater A_p .

Phytoplankton growth and zooplankton grazing in oligotrophic oceans

George A. Jackson

Institute of Marine Resources, Food Chain Research Group, Scripps Institution of Oceanography, University of California, San Diego, La Jolla, California 92093

Central oceanic regions such as the Sargasso Sea and the North Pacific Gyre have traditionally been thought of as biological deserts^{1,2}. New phytoplankton production estimates³ and interpretations of physiological data^{4,5} have suggested that these areas are, in fact, highly productive and that nutrient exchanges supporting these high growth rates are extremely transient. Fast phytoplankton growth rates must be balanced by equally fast zooplankton-caused mortality. Zooplankton abundances and their filtration rates, however, are consistent with slow phytoplankton growth rates, not fast. It is shown here that the dominant grazers in oligotrophic areas seem to be microzooplankton, and that molecular diffusion limits the effect of nutrient pulses, implying that bulk nutrient concentrations are most important. Present growth studies imply that phytoplankton can meet their growth needs with nanomolar ammonia concentrations.

Ambient concentrations of such nitrogenous nutrients as ammonia are below detection limits with conventional chemical methods in surface waters of central oceanic oligotrophic areas^{6,7}. Indirect evidence suggests that the concentrations of ammonia and urea in the North Pacific central gyre⁷ are less than 50 nM. This is far lower than average values for unpolluted coastal waters^{8,9}, and very low compared with half-saturation concentrations for most phytoplankton grown in cultures¹⁰.

Growth rates for phytoplankton growing with steady-state nutrient kinetics at such low concentrations would be low, a fact supported by ¹⁴C incubation measurements in the central North Pacific Gyre. Average specific growth rate, calculated as carbon assimilation rate divided by living carbon concentration⁷, is about 0.1 per day.

Phytoplankton growth measured by other techniques can yield much higher rates. The shortest doubling time reported is 3 h in the Sargasso Sea, calculated from ATP concentration changes in incubated water samples³. This is equivalent to a specific growth rate of 2.8 per day for a 12-h growth day.

Cellular nutrient status determines and can, therefore, indicate growth rate. Phytoplankton grown in cultures have their carbon, nitrogen and phosphorus contents in the same relative proportions as those in oceanic phytoplankton (in the Redfield ratio) only when growing at maximal rates⁵. If the physiology of oceanic phytoplankton is the same as that of

cultured phytoplankton then oceanic cells also grow at maximum rates⁵. Oceanic cells with the same maximum growth rate as cultured cells would grow at 2–3 per day.

These high growth rates cannot be supported for cells growing in a steady state with measured nitrogenous nutrient concentrations. Because slightly N-depleted phytoplankton display elevated uptake rates when compared with N-sufficient algae and because a source of regenerated nitrogen is zooplankton excretion, McCarthy and Goldman⁴ suggested that phytoplankton in oligotrophic oceans may obtain their nitrogen needs by rapid, transient uptake of excreted nitrogen. They noted such nutrients should be present at concentrations well above average in the wakes of swimming animals. They recognised that such elevated concentrations would persist only briefly. Thus, phytoplankton might appear to be growing successfully at the expense of virtually undetectable small-scale nutrient pulses.

The predominant source of phytoplankton mortality in low nutrient input regions such as mid-ocean gyres is zooplankton grazing. Calculation of grazing rates by multiplying typical laboratory-measured filtration rates and field-measured grazer densities (Table 1) shows that microzooplankton, especially protozoa, are dominant herbivores in the loss to grazers of 11% per day (0.11 per day) in the oligotrophic Pacific.

The conclusion that microzooplankton in the North Pacific Gyre are the dominant grazers explains the low rate of zooplankton excretion measured there¹¹. Specific regeneration rate of the macrozooplankton, calculated by dividing 2.4 nM per day nitrogen regeneration rate¹¹ by the 0.2 μM particulate nitrogen concentrations, is 0.012 per day. Microzooplankton feeding at a total filtration rate 5.4 times as fast (Table 1) will increase this rate to 0.007 per day.

Continuous, steady state uptake has specific growth rates equalling specific uptake rates. To achieve a 0.1 per day growth rate, concentrations less than now measurable would be adequate. For example, *Thalassiosira pseudonana* growth rate is 2.6 per day (81% of maximum) for ammonia concentrations at the detection limit, 0.1 μM (refs 22, 23). If growth follows the Monod equation,

$$\mu = \mu_{\max} \frac{C}{C + K_s} \quad (1)$$

with μ the specific growth rate, μ_{\max} the maximum growth rate, C the ammonia concentration, and K_s the half-saturation concentration, then a K_s value of 23.5 nM can be calculated from the above concentration and growth rate. Such a cell could maintain a growth rate of 0.1 per day at an ammonia concentration of 0.8 nM. A growth rate of 2.6 per day would, of course, require 0.1 μM ammonia.

Short term non-steady state ammonia uptake rates can be much faster than growth rates: instantaneous ammonia uptake rates are as high as 15 per day, equivalent to doubling times of 0.05 days or 4.3×10^3 s (ref. 4). Phytoplankton cells would have to take up nitrogen at maximum capacity for this length of time to accumulate enough nitrogen to support one cell division.

Table 1 Biological scales for central N. Pacific Gyre region

	Phytoplankton	Protozoa	Microzooplankton Nauplii	Post-nauplii	Macrozooplankton Copepods	Thaliaceans
Concentrations (C) (individuals per litre)	600,000*	655*	3*	1*	0.1†	$1 \times 10^{-4} \ddagger$
Separation distance (D) (cm)	0.1	1.1	5	10	21	—
Swimming speed (S) (m per day)	—	120§	—	—	1,200	—
Daily path separation (cm)	—	0.01	—	—	0.29	0
Individual filtration rates (ml per individual per day)	—	0.120¶	2#	10#	168**	500††
Total filtration rate (ml per litre per day)	—	75	6	10	16.8	0.05

Total filtration rate is 108 ml per litre per day, equal to a 0.11 per day grazing rate. Separation distance is $C^{-1/3}$. Daily path separation assumes all swimming paths are parallel and equally spaced, $(C^{-1}S^{-1})^{1/2}$.

* Ref. 17; † M. M. Mullin, personal communication; ‡ doliolids are dominant Thaliaceans (J. A. McGowan, personal communication); § ref. 18; || ref. 19; ¶ ref. 15; # ref. 20; ** ref. 21; †† Filtration rate is that of *Doliolletta gegenbaui* (D. Deibel, personal communication).

Fig. 1 Concentrations through time after a plume is created. Concentrations are fractions of original plume concentration. *a*, *b*, *c* show the effect of a 100 μm wide plume which is representative of a copepod's passage. *a*, At centre of plume; *b*, 100 μm from plume centre, 50 μm from initial plume edge; *c*, 1,000 μm from plume centre; *d*, effect of 10 μm wide plume representative of protozoa passage at centre of plume.

Phytoplankton growing at 0.1 per day could meet their nitrogen needs at uptake rates 1% of the maximum 15 per day.

A discontinuous nutrient source would be excreta from animals swimming near a phytoplankter. From the moment the animal excretes them, nutrients diffuse away. A phytoplankter will see a different range of nutrient concentrations depending on where it is relative to the plume. The concentration in a plume with square cross-section can be easily calculated. The relative concentration, f , at a given time after excretion, t , at a distance away from the centre along the centre line, x , for a plume of initial width, $2a$, and diffusivity, D ($= 10^{-5} \text{ cm}^2 \text{ s}^{-1}$),

$$f = \frac{1}{2} \left\{ \text{erf} \left(\frac{a-x}{2(Dt)^{1/2}} \right) + \text{erf} \left(\frac{a+x}{2(Dt)^{1/2}} \right) \right\} \times \text{erf} \left(\frac{a}{2(Dt)^{1/2}} \right) \quad (2)$$

where $\text{erf}(z)$ is the error function of z (ref. 12, p. 56).

The results (Fig. 1) show that even within the plume, nutrient concentrations drop rapidly. Three hundred seconds after a copepod-sized pulse (100 μm across) is released, concentrations have dropped by three orders of magnitude at the pulse centre and are a maximum 0.1 cm away that is $<0.001\%$ of the initial concentration. Molecular diffusion away from protozoan wake will be faster. Concentration at the centre of a 10 μm plume will have dropped to 0.1% of the initial concentration within 0.1 s. Because they will be further from the pulse most phytoplankton will see even lower concentrations.

Ammonia concentration in a plume behind a swimming herbivore can be calculated several ways. A grazer could be viewed as converting the particulate nitrogen in the water it filters to ammonia. By continually converting the 0.2 μM particulate nitrogen⁷ to ammonia, it would leave a trail of 0.2 μM ammonia. This supposes continual conversion. Sporadic excretion would raise concentration in a given pulse but decrease water volume affected. McCarthy and Goldman⁴ calculated that such a sporadic pulse could contain 5 μM ammonia around a copepod. Thus, the maximum nutrient concentration behind a protozoan will have decreased from 200 to 2 nM within 1 s; the same concentration change behind a copepod would occur within 100 s. These times are much shorter than the 4,300 s earlier calculated as the length of time required to accumulate sufficient N for a doubling. Individual nutrient pulses are not sufficient to be the main nitrogen source for phytoplankton.

These calculations neglect concentration decreases caused by nutrient uptake and assume that only molecular diffusion is important. Phytoplankton and turbulence cause concentrations to decrease faster than has been calculated here.

Usefulness of these molecular diffusion calculations depends on nutrient recycling occurring on small scales. Comparison of feeding rates for potential oceanic herbivores shows that small grazers—protozoa and copepods—dominate the larger thaliaceans, accounting for 99% of water filtered. The marine copepod *Paracalanus parvus* incorporates 37% of ingested particulate nitrogen and recycles the rest¹³. If mid-oceanic grazers recycle at the same 63%, then microzooplankton and copepods recycle at least 62% of ingested primary production for uptake by surviving phytoplankton, either directly or through bacteria. Thus, nitrogen cycling occurs predominantly on the microscale. Inputs on a larger scale, from salp aggregates or fish schools, may be more visible but less important.

Importance of nutrient interactions on a small scale is analytically convenient because diffusion-based mixing processes are so much better understood than those based on turbulence. Additionally, the complete range of phytoplankton-herbivore interactions would be occurring at any given time in the medium scale water sample. This would imply that the mean nutrient concentration through time at a given phytoplankter (that is, what a cell sees) would be the same as the mean concentration through space at a given time (that is, a water sample). A linear uptake-ammonia relation would imply that mean nutrient uptake rate is linearly related to the mean concentration through time at the cell, which is in turn linearly related to the measured concentration. As long as uptake rate is a linear function of ammonia concentration, the amount of ammonia will provide a useful mirror of an individual phytoplankter's environment. Less than linear uptake rates, indicative of saturation of cellular systems, would cause a linear model to overestimate cellular nutritional status.

Microzooplankton, which control N cycling in the temporally and spatially uniform central North Pacific Gyre¹⁴, need not dominate elsewhere: in the very heterogeneous coastal California protozoa are relatively unimportant¹⁵. The northern Sargasso Sea, where cold core rings introduce variability not seen in the central Pacific¹⁶, may have different grazers. However, similarity in zooplankton volumes for the North Pacific and the North Sargasso Sea^{14,16} suggest that the two oligotrophic systems are similar.

Why, then, do oceanic phytoplankton show nutritional composition characteristic of nutritionally fit cells? If oceanic algae grow at a rate of 0.1 per day and if the relationship between cellular nutrient status and maximum growth rates found in culture studies⁵ apply to all phytoplankton, then algae from oligotrophic oceanic areas have lower maximum growth rates. This would imply that the algae have adapted to perpetually low growth rates by losing the ability to grow fast. Further understanding of nutrient cycling in these oligotrophic areas will depend on the development of techniques to measure these low concentrations.

This study was funded by the US Department of Energy on contract DE-AM03-76-SF00010. I thank T. Platt, J. Cullen, I. Heaney and especially R. Eppley, J. Beers, J. McGowan, D. Deibel and R. Armstrong for helpful suggestions.

Stromatolites 3,400-Myr old from the Archean of Western Australia

Donald R. Lowe

Department of Geology, Louisiana State University, Baton Rouge, Louisiana 70803

Internally laminated conical mounds characterise a regionally extensive chert unit near the top of the 3,400-Myr old Warrawoona Group in the Pilbara Block of Western Australia. The chert formed by silicification of a carbonate-evaporite sequence deposited in shallow subtidal to intertidal environments. The morphology and internal organisation of the mounds described here suggests that they are conical stromatolites similar but not identical to members of the common Proterozoic group *Conophyton* Maslov.

The Warrawoona Group of the eastern Pilbara region of Western Australia (Fig. 1) is a typical Archean greenstone belt volcanic sequence^{1,2}. The 10-km thick section consists largely of volcanic rocks interstratified with cherty sedimentary units generally <30 m thick. Low greenschist-grade metamorphism has affected the entire sequence, but, in the areas studied, shearing is largely absent. Cherty units commonly show only minor recrystallisation.

During sedimentological studies in the eastern Pilbara, I identified a distinctive stromatolitic chert unit near the top of the Warrawoona Group in at least three of the Pilbara structural belts (Fig. 1). Here this unit is called the Strelley Pool chert for outcrops at Strelley Pool (21°06'33"S, 119°08'14"E) in the Pilgangoora Syncline (Fig. 1). The unit averages a relatively constant 20-25 m in thickness, although it reaches 50 m on the

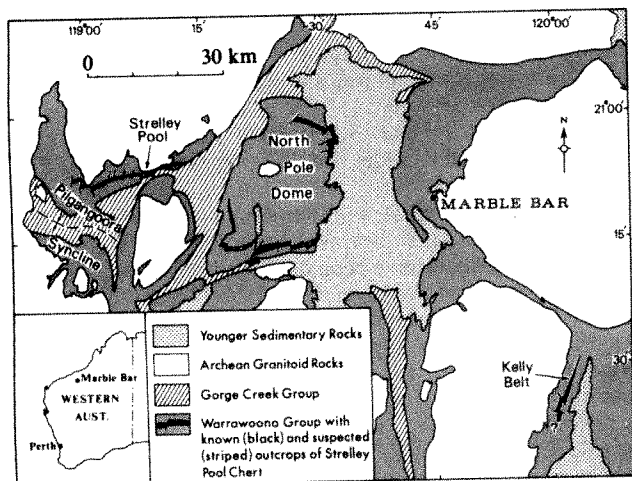

Fig. 1 General geological map of the northeastern Pilbara region showing known and suspected outcrops of the Strelley Pool chert.

Fig. 2 Photomicrograph of alternating light and dark flat laminae from area between conical stromatolites. Arrows point to layers containing detrital quartz grains. Micronodular character of translucent laminae resembles fenestral texture of modern algal mats. Scale bar, 0.5 cm.

north flank of the North Pole Dome (21°00'43"S, 119°28'52"E). An excellent section in the Kelly Belt occurs near Spinaway Creek at 21°35'S, 120°01'01"E.

The Strelley Pool chert displays a nearly constant internal stratigraphy in the three structural belts in which it was identified. It can be subdivided into two main members. The lower 10-15 m consist largely of finely laminated chert. The rock shows thin, varve-like alternating laminae of light grey chert and dark grey carbonaceous and pyritic chert or of calcareous and non-calcareous chert (Fig. 2). The laminae may be flat and even but commonly form isolated or clustered conical mounds here interpreted to be stromatolites. This subdivision characteristically includes units up to 1 m thick composed of massive, coarsely crystalline silicified evaporite. These units are present in every section examined. In the Pilgangoora Syncline, a quartzite layer is present locally at the base of the chert, and thin laminae and wisps of detrital quartz occur irregularly in the overlying laminated chert (Fig. 2). Along at least two horizons, underlying laminae are truncated and cut by desiccation cracks filled with detrital sand, but, overall, coarse clastic layers, current structures, and evidence of exposure are rare. This subdivision was deposited in a subtidal to lower intertidal environment and originally consisted of interlayered evaporite and carbonate sediments.

The upper part of the Strelley Pool chert includes a variety of dark to light grey, white, and greenish cherts. Layers of large silicified evaporite crystals occur towards the base. Large pods of silicified collapse breccia and cavities containing silicified stalactitic and stalagmitic fill indicate the existence of considerably greater amounts of original evaporite and extensive post-depositional exposure, leaching, and solution collapse. Small intraformational conglomerates, scours, and other features

suggest deposition in low energy environments ranging from shallow subtidal to intertidal. In the Pilgangoora Syncline, this unit is capped by detrital volcanoclastic material that may represent alluvial deposits.

The regional consistency of the detailed internal stratigraphy of the Strelley Pool chert across the entire 100+ km extent of its known outcrop (Fig. 1); its distinctive and regionally consistent sedimentology; and the characteristic development of stromatolites are unlike other chert units in the Warrawoona Group and indicate that the Strelley Pool chert is not correlative with better known chert units at Marble Bar and near the base of the North Pole stratigraphic sequence¹. These cherts lie several kilometres stratigraphically below the Strelley Pool chert. The latter represents a single, large, regionally extensive Archean evaporite basin which covered much of the area of the modern eastern Pilbara.

Unbranched, conical, columnar stromatolites occur within the lower subdivision of the Strelley Pool chert across its entire outcrop. They occur as distinct conical mounds with a relief generally between 2 and 6 cm (Figs 3 and 4). Individual mounds may extend vertically through as much as 0.6 m of rock. Apical angles average 70° to 80° (Fig. 4), but are locally as low as 30°. The internal lamination is fine and continuous, even across areas between widely spaced stromatolites. In horizontal sections and rare occurrences where the stromatolites show in relief on bedding surfaces, their shape varies from circular to elliptical (Fig. 3).

These structures are considered to be biogenic for several reasons. Their gross morphology and internal structuring are like those of post-Archean conical stromatolites, particularly members of the group *Conophyton* Maslov^{3,4}. Fine laminae showing alternating light and dark layers are characteristic of many Proterozoic and early Archean unbranched conical columnar stromatolites. However, the Strelley Pool stroma-

Fig. 3 Surface morphology of conical stromatolites in the Strelley Pool chert. Note elliptical shape of many of the larger cones. This specimen from outcrops west of Strelley Pool at 21°08'S, 119°00'28"E. Scale bar, 5 cm.

Fig. 4 Vertical slab through same block of stromatolitic chert shown in Fig. 3. Note slight axial thickening of laminae. Darker areas are calcareous; light areas are nearly pure chert.

tolites differ from true *Conophyton* Maslov in generally lacking a well defined axial zone. Individual laminae instead are continuous across the apical region, showing a slight thickening in most specimens (Fig. 4). Their occurrence in shallow subtidal evaporitic deposits in the Pilbara accords well with previous interpretations that conical stromatolites commonly develop in subtidal environments by alternating periods of organic growth and chemical precipitation^{5,6}. The continuity of the laminae from stromatolite mounds to flat inter-mound areas in the Strelley Pool chert indicates that large areas of the sea floor were covered by flat organic mats. In the Pilgangoora Syncline, the flat cryptogalaminites contain detrital sand grains and sand laminae (Fig. 2), features characteristic of both modern and ancient algal and bacterial mats reflecting their binding and trapping ability.

Lavas from the Duffer Formation near the middle of the Warrawoona Group have been dated at about 3,450–3,490 Myr BP (refs 8, 9). These rocks are 1–2 km stratigraphically below the Strelley Pool chert, and, although the possibility of intervening unconformities cannot be dismissed, the overall igneous and sedimentological continuity of the Group suggests that major hiatuses are absent. Following deposition of the uppermost part of the Warrawoona Group and the suprajacent Gorge Creek sediments, the rocks were extensively deformed and intruded by granitoid plutons. The main period of deformation and associated plutonism has been dated at about 2,900–3,100 Myr (refs 10, 11). The possible age range for the stromatolites is, therefore, 3,450–3,100 Myr, but their close association with the older rocks suggests deposition at ~3,400 Myr.

The importance of the stromatolites in the Strelley Pool chert lies in their implications towards the nature of early life forms. Archean stromatolites have been described previously from the 2,600–2,700 Myr-old rocks in Canada^{12,13}, from the 2,500–2,800 Myr-old Bulawayan Group in Rhodesia^{14,15}, and from the 3,000 Myr-old Pongola Supergroup in South Africa¹⁶. Dunlop and others¹⁷ have previously reported oncolitic and mat-like structures which they interpret to be stromatolites from the Warrawoona Group, but they are apparently of local occurrence, do not show a well developed mound-like habit, and have not been documented as being biogenic.

The Strelley Pool stromatolites are similar in morphology and internal structure to stromatolites from younger Archean and Proterozoic sequences. If these and other Archean stromatolites

represent, at least in part, the activities of blue-green algae, as seem probable based on comparisons with modern stromatolites¹⁸, including *Conophyton*¹⁹, they would substantiate suggestions that photosynthesis was an effective source of oxygen 3,500 Myr ago²⁰. They also imply that the origin of terrestrial life lies much further back in geological time than 3,500 Myr.

This report is based on work supported by the NSF under grant EAR78-01642.

Stromatolites are the least controversial evidence of early life; they are organosedimentary structures resulting from the growth and metabolic activity of microorganisms¹. Before this report, however, the oldest well established occurrence was in the 2,900-3,000 Myr Pongola Supergroup of South Africa²; five or six additional occurrences are known from the later Archean³. The only proposed example from older rocks is of a possibly stromatolitic microfabric from 3,500 Myr cherts in South Africa⁴; as yet that interpretation has not been supported by the discovery of macroscopic stromatolites. Here we describe stromatolites 3,400-3,500-Myr old from the Pilbara Block of Western Australia. These are the oldest firmly established biogenic deposits now known from the geological record.

Only in rocks younger than 2,300 Myr, recording the second half of Earth history, is our understanding of the course of biological evolution closely constrained by palaeontological, geochemical and sedimentary evidence^{5,6}. Objects interpreted as microfossils have been reported from 3,300-3,500 Myr cherts from Australia⁷ and Africa^{4,8,9}, and 3,770 Myr quartzites from Greenland^{10,11}, but none has yet found general acceptance¹²⁻¹⁴. Sulphur and carbon isotope data have been interpreted as indicating that the origin of microbial sulphate-reduction occurred between 2,700 and 3,300 Myr ago¹⁵⁻¹⁷ and that photosynthesising microorganisms may have originated even earlier than the deposition of the oldest known sediments

(3,770 Myr)¹⁸, but as yet relevant data are few and at least in the example of the carbon isotopes are subject to differing interpretations¹⁹. Kerogen is abundant in some Archean sedimentary rocks²⁰, but the interpretation of this is complicated by the fact that carbonaceous substances can be produced abiogenically²¹, as well as by heterotrophic and autotrophic organisms.

Structures resembling stromatolites are abundant in a chert-barite unit in the dominantly ultramafic-mafic metavolcanic Warrawoona Group of the eastern Pilbara Block (Fig. 1). Many of these structures seem to have formed by abiological processes (such as slump folding and silica deposition in voids), and others, while possibly biogenic, are not distinctive enough to be interpreted unambiguously. Earlier studies recorded the presence of possible stromatolitic fabrics²², clasts possibly formed by desiccation of microbial mats (some having oncolite-like overgrowths)⁷ and possible stromatolites²³. The structure we describe here has a relatively complex morphology which provides more criteria for biogenicity.

The chert-barite unit at North Pole consists of bedded shallow water metasediments 40 m thick that persist for at least 30 km along strike^{24,25}. The maximum metamorphic grade is in the lower greenschist facies, and the rocks have been subjected to little strain (ref. 26, and B. James, personal communication). Four sediment types are present: (1) those interpreted as silicified detrital carbonate rocks, often containing relict grains of carbonate and small (up to 1 cm) silica pseudomorphs after gypsum; (2) stratiform barite, some of which can be shown to have replaced evaporative gypsum^{24,25}; (3) silicified mafic volcanoclastic rocks; and (4) those interpreted as primary siliceous sediments, now cherts. A model lead age of 3,420 Myr has been obtained from galena within remobilised barite at this locality (J. Richards, personal communication). The volcanic Duffer

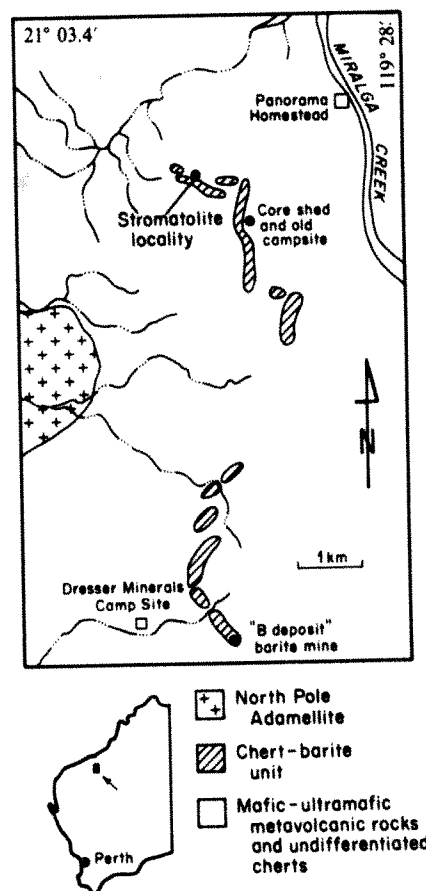

Fig. 1 Map of the northeastern part of the North Pole Dome, eastern Pilbara Block, showing the locality from which the stromatolite was collected. All rock units, apart from the post-tectonic intrusive North Pole Adamellite, are within the Warrawoona Group.

Fig. 2 Field photograph showing the exposed nodular and stratiform portions of the stromatolite. Scale, ~5 cm.

Formation, also within the Warrawoona Group and considered an approximate stratigraphic equivalent of the chert-barite unit²⁶, has yielded zircons that have been dated at $3,452 \pm 16$ Myr (ref. 27), and volcanics lower in the Warrawoona Group have recently been dated at $3,520 \pm 60$ Myr using Sm-Nd (P. J. Hamilton, personal communication).

The stromatolite described here is composed of dolomitic chert and was collected 5 m from the top of a 10.5-m thick exposure of bedded chert in an area of complex faulting 2.5 km WSW of Panorama Homestead (Fig. 1). Discussion of the possible original mineralic composition of the stromatolite is beyond the scope of the present paper. The bed underlying the stromatolite is composed of bands of clear to white chert, white agate, and red finely laminated jaspilite. The bands are separated by laminae of 1–2 mm wide rhombs of ankeritic dolomite. In outcrop, a single nodular structure 20-cm high by 25-cm wide (Fig. 2) was the only domical stromatolite visible; no similar structures were recognised in the same bed. The nodule protruded upward from a 20-cm thick bed of wavy laminated chert with lenses of intraclast and possibly ooid grainstone, into thin-bedded dolomitic chert. A specimen $60 \times 60 \times 40$ cm containing the nodule was collected and cut into slabs about 5-cm thick. This revealed several smaller, wavy laminated nodular stromatolites and a small escarpment encrusted by fine wavy laminae (Fig. 3).

It is apparent that the nodular and wavy laminated forms were primary sedimentary structures with relief, because undeformed overlying and adjacent beds wedge out against, abut against, or thin over the structures, and an erosional scarp has been encrusted by subsequently deposited laminae. The intraclasts found alongside the nodular structures are of two types: the first is thick (3–5 mm), flat, and similar in microstructure to the thin-bedded unlaminated cherts interbedded with the stromatolites; the second is thin (~1 mm) and arcuate to indulose, and indistinguishable in microstructure from the stromatolite laminae. These latter delicate clasts probably could not have survived long transportation, and probably were derived locally from the accreting stromatolite subsequent to desiccation.

The stromatolites have a banded microstructure²⁸ with wavy and wrinkled laminae predominantly 50–200 μ m thick, although many laminae are as thin as 20 μ m (Fig. 4). Domical laminar structures up to 3 cm wide occur frequently within the stromatolites (Fig. 3), and many persist vertically for more than a centimetre, producing pseudocolumnar structures. Many of the ooidal structures are flat-topped, with sharply deflexed margins. Junctions between contiguous domes are V-shaped. Small, discrete columns occur rarely within the large stromatolite nodule. These laminar structures are closely comparable with those of younger stromatolites²⁹.

There are abiogenic structures that resemble stromatolites²⁹, but of all such structures, only one class seems to provide a plausible alternative to the biogenic interpretation of the North Pole structures. That is the possibility that they may be deposits from splashing water, such as the coniatolites described from the Persian Gulf³⁰. However, such an interpretation is not consistent with the abundant occurrence of intraclasts having the same microstructure as the stromatolite (a feature absent from coniatolites because they are not susceptible to desiccation due to their compact, hard nature), or with the absence of dripstone structures, abundant coated grains, and microreticulate ridges on lamina surfaces, features characteristic of coniatolites³⁰. We conclude that the structures are correctly identified as stromatolites. Research on the recognition and distribution of stromatolites in the Warrawoona Group and on the palaeoenvironmental setting, is continuing (R.B. and J.S.R.D.).

It seems that there was a benthic microbiota 3,400–3,500 Myr ago, but its biological affinities are unknown. The common opinion in the literature is that the presence of stromatolites establishes the former presence of cyanobacteria, but that is an unwarranted interpretation, especially for Archean stromatolites^{3,31}. There are living examples of bacterial stromatolites built by other than cyanobacteria, for example, by *Chloroflexus*, a green, photosynthetic, filamentous bacterium which presently constructs stromatolites in hot springs^{31–33}. Furthermore, it is reasonable to suggest that there was a time, before the advent of the appropriate cyanobacteria, when the dominant stromatolite-builders were organisms such as *Chloroflexus*. This is significant because among the bacteria only the cyanobacteria release oxygen during photosynthesis; so at

Fig. 3 Tracings of laminae revealed on sawn slab faces 2ii (parallel to and 13 cm further into the rock from the plane shown in Fig. 2) and A (at 90° to plane of a). The laminae consist of dolomitic chert. Note the three domical structures in the centre of a and the encrusted scarp to the lower left and the pseudocolumnar structures to the central left of b. The stipples represent possible ooid grainstones, the small dashes are intraclasts derived from the stromatolite and the large black tabular bodies are intraclasts derived from the overlying clear to white thinly bedded dolomitic chert. Scale bars, 10 cm.

Fig. 4 Photomicrograph in transmitted plain light of fine (20–100 μm) stromatolitic laminae composed of ferruginous dolomitic chert. Scale bar, 5 mm.

least for these very ancient rocks it is not possible to equate the presence of stromatolites with the former presence of oxygen-releasing photosynthesizers.

No microfossils have been found within the stromatolite, but a consideration of the microstructure allows us to draw some inferences about the morphology of the constructing organisms. As many laminae are as thin as 20 μm , these organisms must have been no larger than that, at least in one dimension. The regular, even, lamination of the stromatolite is comparable with that demonstrably produced by filamentous organisms in other stromatolites, and unlike that produced by coccoid organisms³⁴.

The microbiota seems to have inhabited an environment where it was intermittently exposed to the atmosphere and so inevitably was exposed to UV radiation, severe fluctuations in water potential³⁵, and diurnal temperature changes. Its presence may indicate that a protective ozone screen already existed. The microbiota had developed some strategy for coping with the danger of burial by sediment, which led to the accretion of the stromatolite, but it is not yet possible to say whether the strategy involved phototaxis, as in many younger stromatolites. Already at this very early stage in Earth history, a community of organisms existed that was adapted to life in an adverse, fluctuating environment.

The stromatolite described here was found by J.S.R.D. in 1977 during research for a doctoral project on the North Pole barite deposits. We thank the Bureau of Mineral Resources Geology and Geophysics, Australia, and the Geological Survey of Western Australia, for providing support in the field, and NASA Grant NSG 7489 and the NSF Waterman Foundation Award to J. W. Schopf for financial support. M.R.W. is on leave from the Bureau of Mineral Resources, Geology and Geophysics. J. M. Hayes, H. J. Hofmann, D. Gregg and L. Bettenay assisted with the collection of the specimen on which this study is based. We thank D. I. Groves for supervision and support, and J. W. Schopf, J. M. Hayes and M. Schidlowski for helpful comments.

How do fish break the speed limit?

C. S. Wardle

DAFS Marine Laboratory, PO Box 101, Aberdeen, UK

J. J. Videler

Department of Zoology, Groningen University, Haren, The Netherlands

Many studies have shown that tail beat frequency of teleost fish is closely related to their swimming speed. These findings were developed further by Wardle¹, who showed that maximum tail beat frequency and thus swimming speed could be predicted by measuring the twitch contraction time of the fast swimming muscles. The contraction time increases with the length of the fish and decreases with increase of temperature. Several authors have observed and recorded swimming speeds greater than the predicted speed limit. For example, Stevens and Neil² report that skipjack tuna (*Katsuwonus pelamis* (L), length (L) 0.5 m) could swim at a speed of 10 m s⁻¹ at 32 °C, whereas the maximum predicted speed (extrapolating Wardle's¹ data) was only 8 m s⁻¹. Walters and Fiersteine³ recorded a yellowfin tuna (*Thunnus albacores* (Bonnatare), L = 0.98 m) moving at 20.8 m s⁻¹ and Wahoo (*Acanthocybium solandrin* (Cuvier), L = 1.13 m) at 21.4 m s⁻¹. These two records show just twice the predicted maximum swimming speeds. Unfortunately no observations of the tail beat frequency were made during these high-speed swim records. Brill and Dizon⁴ have shown that five skipjack tuna (L 0.37–0.43 m) had muscle contraction times similar to non-scombroid teleost species of this size measured by Wardle¹. It seems therefore that the tuna family (Scombridae) do not have faster maximum tail beat frequency than other teleosts of the same size and temperature. We show here how this paradox can be solved by the fish using a different swimming style, requiring greater power and efficient interaction between the propelling surfaces and the water, but allowing the fish to move twice as far for each tail beat.

The normal relationship between tail beat frequency and speed can be explained by a simple analysis of the fish's swimming movements. We have analysed² the lateral body movements of cod, *Gadus morhua*, swimming at constant speeds and defined a two-wave system which allowed exact description of swimming movements in most teleost fish. Fish move forwards by means of a series of waves of contraction of the lateral muscles on alternate sides, starting in the myotomes behind the head and ending where the last myotome inserts on the tail. A wave causes lateral displacement of body and fins and these in turn cause forward motion by reaction with the water. During constant speed swimming the speed (v) of the wave moving from head to tail is always slightly greater than the forward swimming speed (u); so that u/v is less than 1. The wave on the body is S-shaped when seen from above and has a measurable wavelength λ_b . The amplitude of the wave is small in the head region and greatest at the tail tip where it is normally 0.2 times body length. The track traced by the tail tip through the water forms a second wave with wavelength λ_s , which is always shorter during constant speed swimming than λ_b , but has the same period (T); λ_s can be much longer or much shorter than λ_b , depending on whether the fish is slowing down or accelerating. It is easy to measure λ_s but measurement of λ_b and its velocity (v) requires accurate identity and location of the wave crests on images of the swimming fish. Towards the head, the amplitude of the wave can be very small and the wave crests difficult to identify. New techniques for filming and accurate analysis enabled us to measure the wave parameters and development of the relationship between the two wave systems discussed before⁵. We confirmed that $u/v = \lambda_s/\lambda_b$. Previous studies have shown that λ_s , which is equal to the distance moved forwards after completion of one tail beat cycle or the passage of one wave, is near to 0.7 times body length (L). For all the species studied, including goldfish (*Carassius auratus*) and tuna, this figure holds, and tail beat frequency gives a straight line when plotted against swimming speed (measured in lengths per second) during constant speed swimming and over a wide range of speeds⁶⁻⁹.

With u/v always slightly less than 1, λ_s always close to 0.7 L and λ_b always longer than λ_s (in cod $\lambda_b = 0.85 L$, ref. 4) it becomes evident that there is relatively little variation in the relation between λ_b and L . All those species where tail beat frequency has been related to constant swimming speeds have therefore shown slightly more than 1 λ_b within the straight body length (L).

Fig. 1 Firm lines represent the wave (wavelength λ_b) on the body of a fish with straight length L . The dashed lines show the track of the tail tip (wavelength λ_s) after one completed tail beat. Note the distance moved forwards after two contractions of the lateral swimming muscles: a, 0.35 L ; b, 0.7 L ; c, 1.4 L .

Fig. 2 Mackerel *Scomber scombrus* L., length 0.345 m, speed 2.9 m s^{-1} , swimming in the style shown in Fig. 1b, printed from 16-mm cine film made at 200 frames s^{-1} (Locam camera). Fish were illuminated with 150-W tungsten lamp, the light source guided by fibre optics to shine from points beside the camera lens to create silhouettes of the fish moving across a marked screen of reflex reflector material (3M high intensity Scotchlite). The reference lines are 25 cm apart. The tail sweeps from left to right in 35–40 ms, a time close to the twitch contraction time at 12°C .

To develop this important point let us compare the normal fish discussed so far with one fish showing two complete waves on its body so that $L \approx 2.2 \lambda_b$ and another fish of the same length but with only half a wavelength on its body so that $L \approx 0.56 \lambda_b$ (Fig. 1). Consider for each case the result of completing one tail beat cycle during constant speed swimming in time T . The track of the tail tip in each case is indicated by the dashed lines, and the distance moved forwards is a different λ_s in each case. In Fig. 1a the fish moves forwards less than 0.35 L . In the normal fish represented by Fig. 1b the forward movement is 0.7 L . In Fig. 1c, showing the fish with $L \approx \frac{1}{2} \lambda_b$, the distance covered is about 1.4 L . That is exactly twice the progress of the normal fish in the same time T . In all three cases the distance moved is the result of one contraction of the right and one contraction of the left lateral swimming muscles. This means that the shortest time in which each of the illustrated manoeuvres (Figs 1a–c) could be completed is twice the twitch contraction time as discussed by Wardle¹. This argument suggests that if L could ever approach or even equal $\frac{1}{2} \lambda_b$, the fish could bound forwards at up to twice the speed of the normal fish using the same contraction time. However, consider the problems of swimming at maximum speed with $L = \frac{1}{2} \lambda_b$. It is reasonable to suppose that normal fish swimming at maximum speed are contracting nearly the whole of the fast, white anaerobic muscle in each myotome in order to develop sufficient force in the wave to counteract the drag of the water on the fast moving body. This force (F) increases with the swimming speed to the power 1.8 where $F = \frac{1}{2} \rho A u^2 1.2 C_f$ (ref. 10). The flow around fish longer than 0.50 m swimming at 5 m s^{-1} at 30°C will be turbulent and C_f , the drag coefficient, will be proportional to $\text{Re}^{-0.2}$ and so proportional to $u^{-0.2}$. F is then proportional to $u^{1.8}$. (Re is Reynolds number, ρ is the density of water and A the body surface area.) The power (Fu) increases with $u^{2.8}$. That means to double the speed, seven times the power is required; equivalent to seven times the volume of swimming muscle. A fish swimming with $\frac{1}{2} \lambda_b = L$ might reason-

ably be expected to have a body diameter three to six times greater than a fish of the same actual length but with $L = \lambda_b$. However, a greater length of each lateral muscle will be involved in developing the movement when $L = \frac{1}{2}\lambda_b$, so this could be an overestimate. The increased muscle power will require extra strengthening of the spinal column and the surfaces which propel the fish must also be able to shed effectively seven times the power. Power consumption has been measured in cod (length 0.73 m) swimming at 3 m s⁻¹ at about 30 W kg⁻¹, and an estimated 100 W kg⁻¹ was required to swim at its maximum speed of 5.5 m s⁻¹ (ref. 10). A cod-like fish swimming at twice this speed might need to dissipate up to 700 W kg⁻¹. The thick body, strong spinal column and stiff high tail blade of the Scombridae does satisfy to some degree these points.

Is there real evidence that fish can swim with a body wavelength longer than the body length? A graph by Magnuson, summarising the relationship between tail beat frequency and swimming speed in the Scombroidei (fig. 16 in ref. 11), shows a series of measurements where at slower swimming speeds the distance moved forwards, λ_s , for completion of one tail beat is greater than one fish length (L). However, as the speed increases λ_s becomes less than 1 L and all the other scombrid data presented in the figure indicate λ_s similar to other teleosts at

about 0.7 L . It is possible that where λ_s was found to be greater than 1 L , the fish were slowing down. Preliminary measurements of films we have made show that the mackerel *Scomber scombrus* L. (Scombroidei) (lengths 0.33 and 0.345 m) swim with a complete 'S' wave on the body (Fig. 2) at 1.17 and 2.9 m s⁻¹ with $u/v = 0.86$, $\lambda_s = 0.76L$ and $\lambda_b = 0.89L$, all parameters similar to those for the cod. The cine film frames (Fig. 2) show the larger fish swimming at 2.9 m s⁻¹, using the swimming muscles close to their twitch shortening time (40 ms, 9°C) with a tail beat frequency of 11 Hz. The observed high speed swimming of some fish species does exceed the speed limit set by current knowledge of fish swimming, which can only be explained if these fish either use a style of swimming where $\frac{1}{2}\lambda_b = L$, or if they have muscle with much shorter contraction time than usual. To establish the truth there is an urgent need to measure the muscle contraction times, particularly of those species and sizes for which claims to high speed have been made, and it is important that future recordings of high speed swimming should aim to include among other evidence a tail beat frequency record.

Evolution of the orang-utan

Richard J. Smith* & David R. Pilbeam

Department of Anthropology, Yale University, New Haven, Connecticut 06520

The common assumption that the lineage leading to modern orang-utans has always been arboreal is based on general principles of irreversibility and parsimony rather than on any direct evidence of postcranial morphology in ancestral species. We argue here that the available evidence, albeit indirect and circumstantial, justifies the concept of a Pliocene orang-utan ancestor at least as terrestrial as the modern chimpanzee.

The fossil record of undoubted orang-utans consists solely of Pleistocene age teeth, found in sites widespread throughout South-East Asia, including the Chinese provinces of Yunnan, Kwangsi, Kwangtung and Kweichow^{1–3} and North Viet Nam (Simonetta, cited in ref. 4). The association of orang specimens at these localities with a Middle Pleistocene *Stegodon-Ailuropoda* fauna contributes little to an understanding of orang-utan evolution, because the species comprising such faunas give evidence of tropical, subtropical and temperate adaptations^{5–8}. If further study of specimens held in mainland China becomes possible, a preliminary report of fossil orang-utans at a site in Shantung Province⁹ could prove significant. This locality is more than 10° in latitude further north than the well-verified south-eastern fossil orang sites, in a region that was partial desert during maximum glacial advances and open grassland during interglacials^{10,11}.

Subfossil orang-utans, dated at 30,000–40,000 BP, have been found on Sumatra and Borneo. The maxillary occlusal surface area has been estimated to be 12.9% larger in the Sumatran subfossil, *P. pygmaeus paleosumatrensis*, than in extant *Pongo*¹².

The Chinese Middle Pleistocene subspecies, *P. p. weidenreichi*, has teeth even larger than those of the Sumatran subfossil^{12,13}. The tooth size of these fossil and subfossil species indicates that either these animals were larger bodied than the living species, with a tooth size to body size ratio that could have been similar to that of extant orangs, or that they were roughly the same body size as modern *Pongo*, but with larger teeth. Both of these conditions imply the existence of a more terrestrial species. The adult male orang-utan is already the largest arboreal animal known, and field observations suggest that larger individuals would have difficulty supporting their weight in trees. If the fossil species was larger than the modern one, adult males, at least, would have been mostly terrestrial.

If, on the other hand, they were animals with larger teeth relative to body size than living orang-utans (who have relatively large teeth among the extant great apes^{14,15}), we are aware of two plausible explanations. First, the large teeth could be a dietary adaptation. This would not be particularly significant evidence for either an arboreal or a terrestrial niche¹⁶. Alternatively, the relatively large teeth could be a consequence of rapid phyletic dwarfing in body size. The Middle Pleistocene orang-utan is a mainland species, while the subfossils and extant species are restricted to islands. It is unusual for mainland and island populations of a lineage to remain the same size¹⁷, and during the Early and Middle Pleistocene a decrease in the body size of large herbivores on islands was common. When body size undergoes rapid reduction, tooth size decreases more slowly^{18,19}, resulting in relative megadonty.

Thus, subfossil orang-utans were probably arboreal (and therefore little if any larger in body size than living orang-utans) for it seems unlikely that 40,000 yr has been sufficient for the modern arboreal specialisations to evolve. Perhaps arboreality developed from semi-terrestrial, semi-arboreal populations on the islands in response to human predatory pressures²⁰, which accelerated body size reductions. The still larger-toothed, larger-bodied Middle Pleistocene mainland orang-utans would have been less arboreal, and more chimpanzee-like in their use of terrestrial habitats.

Additional evidence for our hypothesis comes from an examination of morphology and behaviour of the living species. In social structure and craniofacial morphology, the orang-utan is an odd animal. The sex difference in the body size of orang-utans is among the greatest of all primates^{21,22}. This is usually explained on the basis of aggressive competition between adult males^{20,21,23-27}, even though sexual selection is not clearly indicated by field observations. For example, Horr²⁴ admits that "direct evidence for male competition in the form of dominance or aggressive encounters is limited" and Leutenegger and Kelley²¹ observe that their acceptance of intrasexual selection is "partly based on negative evidence for other selective factors". While allometry²⁸, bioenergetic and reproductive constraints on female size²⁹ or a maximisation of food resources by niche separation due to body size²² remain possible factors, it is also plausible that the sex difference and large body size of orang-utans are remnants ('heritage' characters) of a more terrestrial pattern³⁰ (accompanied perhaps by a different type of social structure, of which we can know nothing).

Several aspects of dental and craniofacial morphology differ from those seen in most primate arboreal herbivores. Orang-utans have high crowned, low cusped (bunodont) cheek teeth with marked occlusal wrinkling, different from those of other catarrhine primates which exhibit well-defined cusps and shearing facets^{31,32}. The enamel on the occlusal surfaces of their cheek teeth is relatively and absolutely thicker than in any other species of living primate yet examined³³. Enamel thickness is relatively thicker on the occlusal surfaces of species of *Macaca*, *Papio*, *Theropithecus* and *Cercopithecus* (*C. aethiops*) than of species of *Colobus*, *Presbytis*, *Alouatta*, *Ateles*, *Pan* or *Gorilla*³⁴. This appears to separate species with potentially more abrasive (omnivorous) diets from those with less abrasive (folivorous, frugivorous) diets. *Pongo* is the apparent exception^{33,34}.

The mandibular condyle of the orang-utan is high above the occlusal plane and the ramus forms a relatively acute angle with the mandibular corpus. The dental arches are relatively forward in position and tilted up³⁵. Although Biegert³⁵ suggests that these changes parallel those seen in *Alouatta* and can be explained by hyolaryngeal specialisations, Hershkovitz³⁶ argues that *Alouatta* craniofacial morphology has nothing to do with hyoid hypertrophy, but rather with masticatory adaptations to herbivorous browsing, and Zingesser³⁷ confirms that several of these features are characteristic of folivory in New World monkeys.

Living orang-utans therefore have unusual (for an arboreal frugivore) dental and craniofacial adaptations. This suggests either that we do not yet have a clear understanding of the relationships between diet and anatomy in living arboreal or frugivorous primates (which is a distinct possibility), or that ancestral orangs were not arboreal frugivores. What they were we cannot say, but that they have retained a number of characteristics from ancestors adapted to doing very different things seems a real possibility.

Consideration of a terrestrial phase in orang-utan evolution goes hand-in-hand with a growing awareness within the past 5 yr that Miocene hominoid evolution is much more complex than envisioned 15 yr ago³⁸. Typical Neogene hominoids (including our hypothetical Pliocene orang-utan) were probably neither forest nor savannah dwellers, but woodland creatures. Most of these species did not resemble living hominoids. Whether some of them are ancestral to living hominoids, or whether they all became extinct without issue, it seems to us that an even wider range of possible evolutionary scenarios must be considered by students of hominoid evolution than was the case a few years ago. Selecting the correct one is probably not possible given the still poor state of the hominoid fossil record. It will not be made easier unless we realise that past hominoid morphologies, distribution and habitats were probably rather different from those of today; that we should not cling too tenaciously to principles of irreversibility or parsimony; that parallelism in hominoid evolution may have been much more widespread than some of

us have thought; and that we should intentionally begin searching for more heterodox explanations.

Dispersal and the sex ratio

Michael G. Bulmer & Peter D. Taylor

Department of Mathematics and Statistics, Queen's University, Kingston, Ontario, Canada K7L 3N6

It has been shown by Fisher that a 1:1 sex ratio should be evolutionarily stable as there would otherwise be a frequency-dependent advantage to the rarer sex¹. Hamilton pointed out that Fisher's argument depends on the assumption of population-wide random mating, and showed that a female-biased sex ratio was expected in a model in which mating occurred within small local subgroups before population-wide dispersal of mated females. We consider here the sex ratio under some other models of dispersal in a geographically structured population.

For simplicity we consider one-dimensional models, and we suppose that the habitat consists of $2M+1$ discrete patches placed round a circle and labelled $-M, \dots, -1, 0, 1, \dots, M$. In our first model we suppose that there is one mated pair in each patch, which produces k offspring and then dies. Male and female offspring disperse a distance j with probabilities p_j and q_j , respectively ($-M \leq j \leq M$). After dispersal, one pair establishes itself in each patch in the next generation, the male and female partners being chosen at random from the individuals in the patch.

To find the sex ratio which is evolutionarily stable, suppose that the pair in patch 0 has sex ratio s (producing sk sons and $(1-s)k$ daughters), while all other pairs have sex ratio r . To see whether the pair in patch 0 is at a selective advantage to other pairs, let the genes of this pair at a typical autosomal locus be coloured red. We shall now calculate then expected number of red genes in mated pairs in the next generation.

After dispersal there are $r(1-p_i)k$ males with no red genes and $sp_i k$ with two red genes in patch j , with corresponding expressions for females. The expected number of red genes in the successful pair in patch j is

$$\alpha_j = \frac{2sp_i}{sp_i + r(1-p_i)} + \frac{2(1-s)q_j}{(1-s)q_j + (1-r)(1-q_j)} \quad (1)$$

The total expected number of red genes in successful pairs in the next generation is $\alpha = \sum \alpha_j$. Writing $\varepsilon = (s-r)$ and then expanding α in a Taylor series we find that

$$\alpha = 4 + \varepsilon \left\{ \frac{2}{r} (1 - \sum p_i^2) - \frac{2}{(1-r)} (1 - \sum q_i^2) \right\} \quad (2)$$

to order ε . The evolutionarily stable sex ratio is the value of r which makes the coefficient of ε zero, given by

$$\frac{(1-r)}{r} = \frac{1 - \sum q_i^2}{1 - \sum p_i^2} \quad (3)$$

[The above argument is only approximate as it does not track the frequency of a gene determining sex ratio from one generation to the next and since we have only sought the value of r which is at a selective advantage over any mutant sex ratio s present in a single patch. We believe that the result is qualitatively correct, but a more exact analytical treatment of this problem would be valuable.]

Equation (3) can be interpreted as meaning that the evolutionarily stable sex ratio is biased in favour of the sex which disperses more widely and/or more evenly. The mechanism underlying this effect is the competition between siblings of the same sex which has been built into the model; siblings of the sex which disperses further (and/or more evenly) are less likely to be in the same patch after dispersal than siblings of the other sex. The equilibrium sex ratio in equation (3) is the point at which the advantage of producing offspring of the sex with less sibling competition is balanced by the disadvantage of producing offspring of the commoner sex. This mechanism also accounts for the female-biased sex ratio in Hamilton's model^{2,3}, as in this case there is competition between brothers for mates but no competition between sisters.

The above model assumes that mating occurs after dispersal (in contrast with Hamilton's model) and that individuals disperse independently of each other. The second assumption is more likely to be satisfied in animals dispersed passively by external physical forces (for example, marine plankton) than in animals which can control their own movement and can therefore mitigate the effect of competition for space by spacing themselves out. The assumption of independent, passive dispersal is also likely to be appropriate for plants; we shall now extend the model to the problem of resource allocation to male and female functions in hermaphrodite annual plants.

As before we suppose that the habitat consists of discrete patches round a circle. One plant grows in each patch, and each plant produces both pollen and seed. Pollen disperses a distance j with probability p_j , the seed in any patch is fertilised at random by the pollen arriving there, and then disperses a distance j with probability q_j . Of the seed arriving in a patch, exactly one is successful in establishing itself as a mature plant in the next generation.

We suppose that a plant can produce either N pollen grains or n ovules or any linear combination of rN pollen grains and $(1-r)n$ ovules ($0 \leq r \leq 1$). The parameter r is the proportion of its resources allocated to male as opposed to female functions, and is the analogue of the sex ratio in dioecious organisms. To find the evolutionarily stable value of r , suppose that a plant in a single patch has a sex ratio s while all other plants have a sex ratio r . Using the argument invoked above, we find that the evolutionarily stable sex ratio is given by

$$\frac{1-r}{r} = \frac{1+p_0 - \sum q_i^2 - \sum p_i q_{i-1} q_i}{1 - \sum p_i^2} \quad (4)$$

This is a rather complicated expression, but it is clearly possible to obtain either a male-biased or a female-biased sex ratio, depending on the relative dispersal distance of seed and pollen. In general, we may suppose that pollen dispersal has a mode at zero, so that $p_0 \geq p_i$. In this case

$$\sum p_i q_{i-1} q_i \leq p_0 \sum q_{i-1} q_i = p_0$$

so that

$$\frac{1-r}{r} \geq \frac{1 - \sum q_i^2}{1 - \sum p_i^2} \quad (5)$$

Comparing equations (3) and (5), we conclude that there is a tendency for the sex ratio to be biased towards male or female accordingly as pollen or seed disperses more, but that in addition there is some bias towards the female (seed production). This can be attributed to the fact that male (pollen) dispersal occurs in the gamete stage before fertilisation, while female (seed) dispersal occurs in the zygote stage after fertilisation.

The above argument places no restriction on selfing. If selfing is avoided, then effective pollen must come from a different plant. The argument goes through as before if we consider only effective pollen, and equation (4) remains valid if we replace p_i by the truncated distribution p'_i , defined by

$$p'_0 = 0 \\ p'_i = p_i / (1 - p_0), \quad i \neq 0$$

In general, the sex ratio will be slightly more male-biased with avoidance of selfing than if selfing is allowed.

We conclude that differential sibling competition is an important factor in determining the equilibrium sex ratio in a geographically structured population, and can lead to a bias in favour either of males or of females. It has been suggested⁴ that sibling mating is a factor which determines departures from a 1:1 sex ratio in this situation, but in our view⁵ sibling mating is only important as an indicator of the competition between brothers for mates. It is not possible to infer a general relationship between the amount of sibling mating or inbreeding and the sex ratio without considering the means by which inbreeding is caused.

Empirical evidence of the effect of sibling competition on the sex ratio has been found in the bushbaby *Galago crassicaudatus*⁶. There seems to be a male-biased sex ratio, which can be attributed to competition between female kin (sisters, and mothers and daughters) for local limiting resources of high quality food required by pregnant and nursing females.

Measurement of gene flow in *Lupinus texensis*

Barbara A. Schaal

Department of Botany, The Ohio State University, Columbus, Ohio 43210

Gene flow, the movement or dispersal of genes within or among populations, is a crucial factor in determining the structure and cohesiveness of species and populations. Spatial restriction of gene flow can lead to non-random mating and to subdivision of a population into genetic neighbourhoods. On the other hand, extensive gene flow over large geographical areas can overshadow the influence of selection, leading to genetic similarity among populations and increased uniformity within a species. The extent and magnitude of actual gene flow are thus relevant to a broad range of disciplines. While the central role of gene flow is widely recognised, actual measurements of gene flow in either plants or animals are few. In plants gene flow can occur via seed or pollen dispersal. Levels of gene flow due to pollen dispersal have usually been inferred, either by marking pollen with a chemical or radioactive label for wind pollinated species or by determining the distribution of pollinator foraging flight distances for insect-pollinated species. Measurements of gene flow via pollen movement in plants have been limited to studies of a few agricultural species, where the minimum separation distance required to isolate stocks genetically was of interest^{1,2}. Here I report the measurement of the pollen component of gene flow in the insect-pollinated species, *Lupinus texensis*, compare the actual gene flow distribution with the distribution inferred from pollinator flight movements, and finally, determine the genetic neighbourhood size of this species from the pollen and seed dispersal distributions. Actual gene flow via pollen is found to be greater than would be inferred from pollinator movement alone. Gene flow and neighbourhood size are nevertheless very restricted.

Lupinus texensis Hook. (Leguminosae), the Texas bluebonnet, is a winter annual plant of widespread occurrence in central Texas. It is obligately outcrossing, and the pollen vectors are bees, predominantly *Bombus pennsylvanicus* and *Apis mellifera*. Seeds of *L. texensis* are dispersed over distances up to 4 m by the explosive dehiscence of the seed pod.

The pollen component of gene flow was studied in an experimental population of *L. texensis* using as genetic markers allozymes of the phosphoglucose isomerase-1 locus (*Pgi-1*). The *Pgi-1* locus is variable in natural *L. texensis* populations which often contain as many as five mendelian alleles. Flowering plants grown in a greenhouse from field-collected seeds were assayed

Fig. 1 Gene flow and pollinator foraging distances in *Lupinus texensis*. Gene flow (solid bars) is plotted as the frequency of foreign alleles (either *Pgi-1^f* or *Pgi-1^s*) detected in the F_1 progeny of plants located at a given distance. Pollinator moves (open bars) are plotted as the frequency of the total pollinator moves to a given distance.

Fig. 2 Seed dispersal in *Lupinus texensis*. Seed dispersal is plotted as the number of seeds dispersed to a given distance.

for *Pgi-1* genotype and used to construct an experimental population. The experimental population comprised 91 plants spaced uniformly 0.6 m apart in a hexagonal array. Based on the behaviour of pollinators in natural populations, this array was chosen to be large enough for bees to forage without constraint. The centre of the population consisted of a core of seven plants homozygous for an electrophoretically rapidly migrating allele, *Pgi-1^f*. Along one margin of the population were plants homozygous for a slowly migrating allele, *Pgi-1^s*, while the body of the population consisted of plants homozygous for an electrophoretically intermediate allele, *Pgi-1^m*. Bees were allowed to forage freely on the plants in the experimental population for 3 days. During this time the distribution of pollinator flight distances between plants was recorded as a base for an inferred estimation of pollen gene flow. After the experimental period plants were returned to the greenhouse and the resulting fruits were marked. Of the F_1 progeny that resulted from pollinations during the experimental period 746 were assayed for *Pgi-1* genotype. Actual pollen gene flow was measured by detecting heterozygous F_1 progeny, *Pgi-1^{m/f}* if gene flow occurred from the centre of the population, or *Pgi-1^{m/s}* if gene flow occurred from the population margin.

Figure 1 presents the combined gene flow curves and the pollinator foraging flight distribution for the experimental population. Most of the pollinator moves and most gene flow are over very short distances. The actual movement of genes in the population is greater than would be inferred from the pollinator flight distribution alone. Mean gene movement, 1.82 ± 0.10 m, is almost twice as far as the mean pollinator flight distance, 0.97 ± 0.08 m. There were no significant differences between gene flow from the margin and from the centre of the population ($\chi^2 = 8.62$, $P > 0.05$). The shapes of both the pollinator flight distribution and the gene flow curve are leptokurtic, $g_2 = 11.7$ and 3.0 , respectively ($P < 0.05$). The curves differ significantly in relative proportions at each distance ($\chi^2 = 427.3$, $P < 0.05$). The disparity between the two curves is a consequence of pollen carryover from one plant to the next. Pollen carryover occurs when not all of the pollen a bee deposits on a stigma is from the flower just visited; some fraction comes from flowers visited before the most recent. Despite pollen carryover by pollinators, gene dispersal via pollen is still restricted, most gene movement being to neighbouring plants.

As gene movements by both pollen and seed are determinants of genetic neighbourhood size, the seed dispersal distribution was determined for *L. texensis*. Plants whose fruits were ripe and ready to dehisce were placed in an unobstructed area, and the actual distance of seed dispersal from parent plants was measured for 263 seeds (Fig. 2). The seed dispersal distribution is leptokurtic ($g_2 = 5.5$, $P < 0.05$), and the mean seed dispersal distance is 0.58 ± 0.04 m. Seed dispersal as well as pollen dispersal is also restricted; most seeds move but a slight distance from the parent.

Restricted gene flow within a population, such as that observed here, results in non-random mating within the population as a whole. Wright has defined the neighbourhood as that subunit of a population within which there is random mating

(panmixia)³. As there is a significant difference between the estimated gene flow from pollinator foraging distances and actual gene flow, it is of interest to know how such differences influence neighbourhood size. Neighbourhood size, N_e , is defined as the number of individuals which compose a panmictic unit, and its value is estimated by:

$$N_e = 3.6D \left(\frac{\sum p^2}{2N_p} + \frac{\sum s^2}{N_s} \right)$$

where p is the dispersal distance of genes via pollen, s is the axial seed dispersal distance, N_p is the number of pollen dispersed genes, N_s the number of seeds and D is the flowering plant density⁴. Neighbourhood size estimates are generally derived most reliably from data of experimental populations. These estimates have meaning in natural populations as well, as the nature of gene flow is determined predominately by inherent characteristics of the species, such as its modes of pollination and of seed dispersal. Except at the extremes of density, gene flow is influenced only minimally by the distribution of individuals peculiar to a given site.

In the experimental population of *L. texensis*, neighbourhood size, based on gene flow estimated from pollinator movement, is 42.2 plants and neighbourhood area is 2.8 m². The neighbourhood size based on actual gene flow is more than twice as large, 95.4 plants, and the area is 6.3 m². Pollen carryover thus has a significant effect on actual neighbourhood size.

The distribution of pollinator flight distances provides only a minimal estimate of the pollen component of gene flow in *Lupinus texensis* and most likely, in other plant species as well. Actual gene flow distance somewhat exceeds that predicted from pollinator flight distribution alone. However, gene flow due to pollen movement is still very restricted spatially. In this study, no gene migration from one margin of the population to the other was detected. The restriction of gene flow is manifest in the small estimates of neighbourhood size and area. A large body of theoretical work predicts that such limited gene flow will greatly influence the genetic structure of populations^{5,6}. As natural populations of *L. texensis* are typically orders of magnitude greater in size than the estimated neighbourhood size—often larger than 10,000 individuals and covering several hectares—they are likely to be subdivided into many neighbourhoods. Such populations are not panmictic, and should exhibit such properties as significant genetic heterogeneity, isolation by distance, and possibly inbreeding.

Serotyping *Plasmodium falciparum* malaria with S-antigens

R. J. M. Wilson

Division of Parasitology, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

The heat-stable proteins known as S-antigens which are associated with *Plasmodium falciparum* malarial infections in man show considerable serological diversity¹. Usually, different S-antigens appear in separate malarial episodes in individuals exposed to reinfection². The antigens have a worldwide distribution in endemic areas but the restricted number and characteristic specificity of S-antigens recovered from experimentally infected *Aotus* monkeys suggest that these antigens might provide suitable markers for serotyping isolates of *P. falciparum*³. Two kinds of evidence to support this idea are presented here. First, S-antigens which characterise an isolate of parasites are shown to retain their specificity over long periods of passage either *in vivo* or *in vitro*. Second, predictable mixtures of S-antigens can be recovered from cultures of *P. falciparum* after deliberately mixing isolates which each give rise to characteristic S-antigens.

The human isolates of *P. falciparum* described in this work were obtained by sampling at random acutely infected children attending the outpatients clinic at the MRC Laboratories in The Gambia, West Africa. Plasma from each blood sample was stored frozen until tested for S-antigen content by gel diffusion. S-antigens were identified by their stability to heating at 100 °C for 5 min⁴. Washed infected erythrocytes from each patient were cryopreserved in glycerol buffer at –196 °C and subsequently thawed and reconstituted by a simplified method⁵. The thawed infected erythrocytes were cultivated *in vitro* with human red cells of blood group A or O (ref. 6). The medium consisted of RPMI 1640 with 15% serum and was changed twice daily. The gas phase was 5% O₂, 7% CO₂, and 88% N₂. Pools of waste culture fluid were centrifuged at 950g to remove cellular debris and were concentrated 10-fold by negative pressure dialysis. Plasma samples were also collected from *Aotus*

monkeys infected with various named isolates of *P. falciparum*, through the courtesy of Dr W. Collins, C.D.C. Atlanta, Georgia. In other experiments, an isolate of *P. falciparum* was serially passaged through splenectomised squirrel monkeys (*Saimiri* sp.), in collaboration with Dr M. Hommel, Institut Pasteur, Paris.

The long-term stability of S-antigen expression was tested using the Ugandan Palo Alto line of *P. falciparum* which has two main S-antigens (Table 1). After more than 10 passages through *Aotus* monkeys, this line of parasites was cultivated *in vitro* in human erythrocytes for 1 month. The parasites were then passed serially through two previously infected (partially immune) *Aotus* monkeys which developed low-grade parasitaemias. The parasites which emerged were transferred by direct blood passage to splenectomised squirrel monkeys and underwent 29 serial transfers before propagation in cultures of human red cells for a further month. Finally the parasitised erythrocytes were inoculated into a squirrel monkey to produce an acute infection. The S-antigens in the plasma of this animal as well as from several of the previous squirrel and *Aotus* monkeys and also from concentrated culture fluids were compared serologically. No alteration was detected in the S-antigen specificities throughout these manipulations. Although selection of parasites

Fig. 1 Production of predicted S-antigens by three lines of *P. falciparum* cultivated *in vitro*. *a*, Plasma from *Aotus* monkey infected with Palo Alto line. *b*, *c*, Plasmas from two different human infections. *a/b* S-antigens from a mixed culture of *a* and *b* parasites. *a/c* S-antigens from a mixed culture of *a* and *c*, with *c* in a minority. *Ab*, Antiserum from an immune Gambian adult.

might have occurred at several points during the series of passages, it appeared that some of the original parasite type persisted. No new type was found despite screening with several heterospecific antisera known to react with a wide variety of S-antigens.

It is necessary to point out here that different S-antigens can be demonstrated in different lines of *P. falciparum* adapted to the *Aotus* monkey (Table 1). However, the frequency of antigen specificities 7 and 8, previously demonstrated in the Malayan Camp strain⁷, is unexpectedly high—four of nine *Aotus*-adapted isolates examined (44%). The same antigens occurred in only 16% of 50 malarious children tested at random. More surveys on these lines are desirable because recent immunological tests^{8,9} with *Aotus*-adapted lines of *P. falciparum* have been made on the assumption that lines with different names are serologically distinct.

It is not established clearly yet whether S-antigens are a direct product of the parasite genome or a host component modified in some unspecified way inside the parasitised erythrocyte. To demonstrate that different lines of *P. falciparum* express their characteristic S-antigens when grown in erythrocytes from a single source still would not indicate their parasite origin unambiguously. However, such an experiment would strongly support the hypothesis drawn from epidemiological and other studies that different S-antigens are characteristic of different isolates of parasites.

To carry out this experiment, plasma samples from 30 acutely infected Gambian children were screened to find appropriately reactive S-antigens and to select those with different specificities. Cryopreserved infected erythrocytes from the selected isolates were reconstituted and cultivated *in vitro*. Examination of concentrated culture fluids from the different lines confirmed that the expected S-antigens were present. Two of these recently derived human lines of *P. falciparum* were then mixed individually with the Palo Alto line to produce mixed cultures. Gel diffusion analysis of concentrated culture fluids

from each mixed culture showed that they now contained the predicted mixture of S-antigens (Fig. 1).

These studies suggest that S-antigens can be used as stable markers of isolates of *P. falciparum* grown either in experimental hosts or in cultures. The findings support our earlier hypothesis¹ that S-antigens reflect considerable diversity in natural populations of *P. falciparum* and that mixed infections with different types occur commonly. This last point has also been confirmed by the demonstration of mixed isozymes of parasite glycolytic enzymes in extracts of infected erythrocytes¹⁰. S-antigens, however, provide a much more extensive marker system than the isozyme and drug resistance differences described by others. Immunological experiments on selective destruction of parasites producing different S-antigens in mixed cultures might throw light on the question of strain specific immunity to *P. falciparum* for which there is evidence in experimental infections of man¹¹ and the *Aotus* monkey^{8,12}.

Mouse C_{μ} heavy chain immunoglobulin gene segment contains three intervening sequences separating domains

K. Calame*, J. Rogers†, P. Early*, M. Davis*, D. Livant*, R. Wall† & L. Hood*

*California Institute of Technology, Division of Biology, Pasadena, California 91125

†Molecular Biology Institute, Department of Microbiology and Immunology, UCLA School of Medicine, Los Angeles, California 90024

The IgM molecule is composed of subunits made up of two light chain and two heavy chain (μ) polypeptides. The μ chain is encoded by several gene segments—variable (V), joining (J) and constant (C_{μ})^{1,2}. The C_{μ} gene segment is of particular interest for several reasons. First, the μ chain must exist in two very different environments—as an integral membrane protein in receptor IgM molecules (μ_m) and as soluble serum protein in IgM molecules into the blood (μ_s). Second, the C_{μ} region in μ_s is composed of four homology units or domains ($C_{\mu}1$, $C_{\mu}2$, $C_{\mu}3$ and $C_{\mu}4$) of approximately 110 amino acid residues plus a C-terminal tail of 19 residues^{3,4}. We asked two questions concerning the organisation of the C_{μ} gene segment. (1) Are the homology units separated by intervening DNA sequences as has been reported for α (ref. 5), γ_1 (ref. 6) and γ_{2b} (ref. 7) heavy chain genes? (2) Is the C-terminal tail separated from the $C_{\mu}4$ domain by an intervening DNA sequence? If so, DNA rearrangements or RNA splicing could generate hydrophilic and hydrophobic C-terminal tails for the μ_s and μ_m polypeptides, respectively. We demonstrate here that intervening DNA sequences separate each of the four coding regions for C_{μ} domains, and that the coding regions for the $C_{\mu}4$ domain and the C-terminal tail are directly contiguous.

Fig. 1 Restriction map and sequences of p104E μ 12. The double-stranded cDNA segment was originally inserted into the *Pst* site of pBR322 by a dC-dG tailing procedure which reconstituted the *Pst* sites at each side¹⁶ (W. Rowenkamp and R. Firtel, personal communication). Mapping was initially done by multiple digests of the whole plasmid. To locate *Mbo*II sites and to confirm some *Sau*3A1 and *Hae*III sites, isolated restriction fragments were 5' end-labelled, cut to separate the labelled ends, and partially digested with the appropriate restriction enzymes. DNA sequences (in regions indicated by arrows) permitted the map to be aligned with the C μ amino-acid sequence⁴.

All the restriction sites mapped are consistent with the coding sequence. There are no sites in the insert for *Eco*RI, *Bam*HI, *Kpn*I or *Xba*I. A and B show DNA sequences from p104E μ 12. Sequences were obtained by the method of Maxam and Gilbert¹⁷, with minor modifications using the 5' end-labelled restriction fragments indicated in the restriction map. Sequence A was determined in one direction only; nucleotides printed in lower case type were ambiguous and have been supplied from the coding requirements. Sequences B was determined in both directions and was unambiguous.

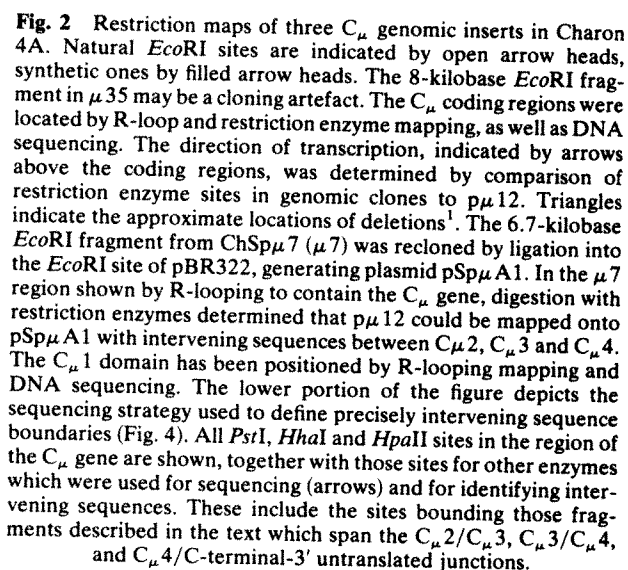

A recombinant plasmid, p104E μ 12 (p μ 12), containing a cDNA sequence from the heavy chain mRNA of the IgM-producing myeloma tumour, M104E, was constructed and characterised by restriction mapping and partial DNA sequence analysis (Fig. 1). A comparison of these DNA sequences with the protein sequences of the M104E myeloma μ chain⁴ indicates that p μ 12 contains C μ coding sequences extending from residue 300 to the C-terminus of the μ chain at position 576. The codon for the C-terminal tyrosine is followed immediately by a stop codon (UGA).

The p μ 12 probe was used to screen several genomic libraries constructed in the vector Charon 4A—a partial *Eco*RI library from the DNA of IgA-producing myeloma M603 (refs 5, 8), a partial *Eco*RI germ-line library from mouse sperm DNA¹ and a partial *Hae*III+*Alu*I germ-line library from sperm DNA¹. Southern blot analyses of *Eco*RI-digested mouse sperm and M603 DNA using the p μ 12 probe showed identical 12.2-kilobase C μ bands¹. This suggests that both the myeloma and germ-line libraries contain the C μ gene segment in the germ-line or unrearranged state. Figure 2 shows the restriction enzyme patterns of three genomic clones. ChSp μ 27 (μ 27) from the sperm library and Ch603 μ 35 (μ 35) from the M603 library contain *Eco*RI restriction fragments of 10.2 and 9.8 kilobases, respectively, which hybridise to the p μ 12 probe. The μ 27 and μ 35 *Eco*RI fragments are slightly smaller than the 12.2-kilobase band observed in *Eco*RI-digested sperm and M603 DNAs. We believe that this discrepancy is caused by deletions in genomic DNA flanking the C μ gene segment which occurred during growth or amplification of the recombinant phages¹. Preliminary Southern blot comparisons of germ-line and μ 27 DNAs localise these deletion(s) to within 1 kilobase 5' to the C μ coding region (M. D., unpublished results) (Fig. 2). A similar result has been obtained by others with C μ -containing clones isolated from a mouse liver DNA library (F. Blattner and N. Newell, personal communication). However, as we show below, the C μ coding sequences of each clone are identical within the limits of our analyses and presumably represent the true germ-line arrangement of the C μ gene segment.

R-loop analyses using heavy chain mRNA from myeloma tumour M104E were performed and similar results were

obtained for all three genomic clones. Representative electron micrographs are shown in Fig. 3. A total of 90 R-loop molecules were analysed, 62 from μ 35 DNA and 28 from μ 27 DNA. A small number of the molecules (6%) showed four single-stranded DNA loops of approximately equal length which we interpret to be four C μ coding regions separated by small, base-paired intervening sequences (Fig. 3a, b). A larger fraction (74%) showed two or three loops, indicating that one or two of the intervening sequences were base-paired while the others remained single-stranded. Often a small bulge appeared at a reproducible point in the double-stranded DNA-RNA hybrid, indicating the position of the single-stranded intervening sequence (Fig. 3d). The remaining 20% of the R-loop molecules showed one large loop. Most of these had small bulges in the double-stranded portion at the positions of one or more single-stranded intervening sequences. The total length of the four coding regions was 1.6 ± 0.2 kilobases and the average size of the loops was 375 ± 51 , 364 ± 58 , 361 ± 60 and 369 ± 73 base pairs. The size of the three intervening DNA sequences could not be accurately determined by this procedure. In addition, R-loop measurements located the C μ coding region $\sim 3.6 \pm 0.36$ kilobases from the 3' end of the 9.8-kilobase *Eco*RI fragment of μ 35. The R-loop structures that we observe indicate that the C μ gene contains three intervening sequences which seem to separate regions coding for the four structural domains of the μ heavy chain.

The coding regions were located more precisely by restriction mapping (Fig. 2). We mapped *Hinf*I, and *Sau*3A1 sites in the region of the four C μ domains in order to measure the sizes of the intervening sequences. A *Sau*3A1 fragment spanning the C μ 2–C μ 3 junction is 331 base pairs long in the p μ 12 cDNA clone and 620 base pairs long in the germ-line clone ChSp μ 7 (μ 7). Therefore, an intervening DNA sequence of 289 ± 15 base pairs exists between C μ 2 and C μ 3. A *Hinf*I fragment spanning the C μ 3–C μ 4 junction is 122 base pairs long in the cDNA clone and 230 base pairs long in the germ-line clone, while a *Sau*3A1–*Pst*I fragment is 147 and 254 base pairs long in the two clones, respectively. Accordingly, there are 108 ± 10 base pairs of intervening sequence between C μ 3 and C μ 4. The C μ 1–C μ 2 junction was not available in a cDNA clone, but the entire

All of the boundaries of the coding and intervening sequences in the C_μ gene segment were sequenced using the strategy shown in Fig. 2. Figure 4 gives the sequences of the splice sites and shows that there is terminal redundancy about each of the intervening sequences. At the downstream splice sites between J_H and $C_\mu 1$, and between $C_\mu 1$ and $C_\mu 2$, the noncoding sequence is identical to the preceding coding sequence for 7 and 8 nucleotides, respectively, before the indicated splice points. The precise splice points can be designated according to the $\text{the/GT} \cdots \text{AG/rule}^9$, and the junction sequences are then found to conform generally to the 'consensus' RNA splicing sites (Fig 2)⁹⁻¹². The intervening sequences occur in codons 127, 230, 340 and 446. These are identical to the C_μ domain boundaries as far as they could be determined from protein sequence homologies⁴.

Restriction mapping also indicates that the C_μ 4 coding region and the C-terminal tail are not separated by an intervening sequence but are continuously encoded in the germ-line DNA. This junction is spanned in μ 12 by a *Pst*I-*Hha*I fragment (Fig. 1), which is 297 base pairs long according to the coding requirements. The corresponding fragment from a subclone of μ 7 (Fig. 2) co-migrates with the μ 12 fragment to an accuracy of ± 15 base pairs. This fragment was isolated from the μ 7 sub-

Our current observations on the C_{μ} genomic clones, in conjunction with previous studies on C_{α}^5 and $C_{\gamma 1}$ and $C_{\gamma 2b}$ genomic clones, suggest that all immunoglobulin C_H genes will contain intervening sequences separating the regions coding for structural domains. Although the function of intervening sequences in eukaryotic genes remains unclear, their positioning precisely at the interdomain boundaries of immunoglobulin C_H genes suggests that the positions of the intervening DNA sequences may have some role in the evolution of immunoglobulin genes. As individual immunoglobulin domains probably encode dis-

tinct functions, the presence of intervening DNA sequences at the domain boundaries may facilitate the rearrangement of domain coding regions and thereby generate new combinations of heavy chain domains for selection, thereby speeding up the evolution of immunoglobulin genes^{8,13}. Alternatively, it also has been proposed that intervening DNA sequences inhibit recombination and, accordingly slow the evolution of eukaryotic genes^{14,15}.

Our studies on the organisation and structure of the C_{μ} gene segment place several constraints on models for the difference between μ_m and μ_s chains. First, Southern blot analyses of embryo or germ-line DNA with the μ 12 probe show only strongly hybridising bands corresponding to a single C_{μ} gene segment which is present in the μ 35, μ 27 and μ 7 clones. This is true for digests with *Eco*RI or *Hinc*II (ref. 1), as well as for *Bam*HI or *Hha*I (M. D., unpublished results). We have isolated 10 independent genomic clones which hybridise to μ 12, and all of these seem to contain the same C_{μ} gene segment (M. D., K. C. and P. E., unpublished results). Thus, these restriction mapping and gene cloning results strongly suggest that there is only one C_{μ} gene segment in the BALB/c genome. If so, the μ_s and μ_m chains must be encoded by the same C_{μ} gene segment. Second, a DNA rearrangement during B-cell development to generate alternative $C_{\mu m}$ and $C_{\mu s}$ gene segments is unlikely. In B-cell development, the μ_m chain is expressed before the μ_s chain. Thus, a putative DNA rearrangement should alter the 3' structure of the expressed $C_{\mu s}$ gene segment. However, our results show that the 3' end of the C_{μ} gene in the μ 12 cDNA clone is identical to the 3' end of the C_{μ} gene in the μ 7 germ-line clone, thus ruling out the possibility of a DNA rearrangement at the 3' coding region of the $C_{\mu s}$ gene segment. Finally, we can rule out a simple post-translation cleavage of a larger μ_m chain to create the μ_s chain because the μ_s coding sequence is followed immediately by a stop codon (Fig. 1).

Two models to explain the origins of μ_m and μ_s still appear plausible: (1) the μ_m chain is generated from the μ_s chain by a novel type of post-translational modification; and (2) a different COOH-terminal coding region for the μ_m chain does exist. A large nuclear RNA transcript could give rise either to μ_s mRNA or, alternatively, to μ_m mRNA by RNA termination, cleavage and/or splicing. We are currently studying the μ RNAs from a B-cell lymphoma which produces only membrane IgM to test these models.

Malignant blast cells in the various forms of acute leukaemia seem to be 'frozen' at early stages of haematopoietic and lymphoid cell maturation. These blasts express relatively stable morphological, enzymatic and antigenic phenotypes which may largely represent the normal gene products of the corresponding precursor cells¹⁻⁴. A number of findings support these suggestions. The phenotype of the common form of acute lymphoblastic leukaemia (cALL) corresponds to the phenotype of normal small non-T, non-B cells of lymphoid morphology detected in low numbers in the normal and regenerating infant bone marrow^{4,5}. Also, the phenotype of blast cells in Thy-ALL corresponds approximately to that of cortical thymocytes or their immediate precursors⁶⁻⁹. Leukaemia-specific (virus-induced or mutant) changes or aberrant expression of normal gene products may also occur in leukaemia. To describe such phenomena, detailed single cell studies comparing leukaemic cells with their appropriate normal (frequently very rare) counterparts are needed. In this study we have performed such a comparative study and find that the human Thy-ALL blasts express unexpectedly high amounts of HLA-A, -B and -C antigens: the sensitive single cell assays used failed to find normal cells (in infant and fetal thymus, and in bone marrow) which express the exact phenotype of Thy-ALL blasts.

Both cALL and Thy-ALL blast cells express large amounts of terminal deoxynucleotidyl transferase (TdT). This nuclear enzyme can be labelled by purified rabbit antibodies to TdT in

Fig. 1 Expression of HLA-A, -B and -C antigen and terminal transferase (TdT) on thymic ALL (leukaemic) blast cells and on normal thymocytes. Cells were incubated with W6/32 antibody (detecting core determinants of HLA-A, -B antigens)¹¹, washed and labelled with goat anti-mouse Ig-TRITC (red). The cells were smeared in a cytocentrifuge and restained for nuclear TdT by purified rabbit anti-TdT antibody¹⁰ followed by washing and a goat-anti-rabbit-Ig-FITC second layer (green). The preparations were photographed by filters selective for TRITC (HLA-A, -B and -C) and FITC (TdT). MT: putative medullary thymocytes. Additional studies have shown that in both Thy-ALL and thymocyte suspensions >95% of cells were strongly positive with anti-T cell serum (HuTLA⁺) and negative with anti-Ia antisera (Ia⁻)⁵.

Fig. 2 In the normal human bone marrow T lymphocytes (HuTLA⁺, TdT⁻; arrows) and TdT⁺ precursor cells (HuTLA⁻, TdT⁺; asterisks) represent different populations. Cells were incubated with rabbit anti-HuTLA, labelled with goat-anti-rabbit-TRITC (red) and smeared. This was followed by restaining with rabbit anti-TdT and goat-anti-rabbit-FITC (green). Additional studies have shown that TdT⁺ bone marrow cells are HLA-A, -B and -C positive (<99%) and mostly Ia⁺ (>85%). None of these cells express HTA-1 (thymocyte-specific) antigen (see ref. 5).

indirect immunofluorescence (IF) test using fluorescein (FITC)-conjugated goat anti-rabbit immunoglobulin as second layer¹⁰. The test can conveniently be combined with other IF tests for various membrane or cytoplasmic antigens using tetra-rhodamine (TRITC)-labelled reagents (Table 1) and has been used both for the diagnosis of leukaemia and for the analysis of early lymphocyte maturation in man^{5,8}. Here, the comparative single cell assays on leukaemic and normal TdT-positive populations indicate that a large proportion of Thy-ALL blasts show anomalous phenotypic characteristics which could not be observed on normal TdT positive infant cells and fetal thymocytes.

The first relevant point was shown in suspensions of normal infant thymus labelled for nuclear TdT and core determinants of HLA-A, -B and -C antigens (using W6/32 monoclonal antibody; Fig. 1). No TdT⁺ cells had detectable HLA-A, -B and -C antigen in over 2,000 thymocytes analysed. These TdT⁺ cells

were cortical thymocytes expressing HTA-1, which is a cortical thymocyte-specific antigen (a possible homologue of mouse TL antigen¹²). Then the study was extended to the relatively rare (1-3%) TdT⁺ lymphoblasts in the infant thymus. These cells express only moderate amounts or no HTA-1 (ref. 8). When stained with Giemsa, these large blasts show a dark blue cytoplasm (putative infant pro-thymocytes). More than 400 of these TdT⁺ blasts were analysed but no HLA-A, -B, or -C positive blast cells were seen. On the other hand TdT⁻ (medullary; HTA-1⁻) thymocytes were brightly HLA-A, -B and -C positive. Thus the expression of TdT and HLA-A, -B and -C in normal thymocytes seems to be mutually exclusive for all the cells of the human thymus.

In marked contrast, in all six cases of Thy-ALL studied as well as in the Thy-ALL cell line studied (HPB-ALL; see phenotypic characteristics in Table 1) TdT⁺ blast cells expressed moderate to large amounts of HLA-A, -B and -C (Fig. 1). This was in spite

Viable cell suspensions were labelled with various antisera (see below) in indirect immunofluorescence test using tetrahydroamine (TRITC)-labelled second layers. Of the membrane-labelled cells smears were made in a cytocentrifuge and fixed for 30 min in cold methanol. These fixed smears were incubated with rabbit anti-TdT antibodies (eluted from TdT antigen column; ref. 10), washed and stained with goat anti-rabbit immunoglobulin labelled with fluorescein (FITC). The nuclear TdT staining (FITC) is easily distinguishable from the membrane staining (TRITC). The study was focused on the TdT⁺ cells in the different samples and the TdT⁻ cells were ignored. The samples studied contained different proportions of TdT⁺ cells (as shown). NT, not tested.

*Results are expressed as cells stained with membrane markers within the TdT⁺ population studied.

†The antibodies used (as first layers) to detect membrane markers were as follows: anti-HLA-A, -B and -C antibody was a mouse monoclonal reagent, W6/32, detecting a core HLA-A, -B and -C antigenic determinant, and was used as culture supernatant at 1:10 final dilution; anti-HuTLA serum was a rabbit anti-monkey thymocyte serum absorbed with human red cells, B lymphoid and myeloid leukaemic cells⁵ and used at 1:25 final dilution; a rabbit anti-Ia-like serum was made in chickens against purified human Ia-like (p28,33) antigens⁵ and was used at 1:25 dilution; anti-HTA-1 antibody was a mouse monoclonal antibody NA1/34, specifically reactive with human cortical thymocytes¹², and used as peritoneal exudate at 1:400 final dilution⁸; anti-HLe-I reagent was also a monoclonal antibody (2D1), strongly reactive with thymocytes and T and B lymphocytes, while only weakly reactive with myeloid cells. This latter antibody was used in the form of culture supernatants at 1:5 final dilution⁸. The second layers (goat-anti-mouse-Ig-TRITC, goat-anti-rabbit-Ig-TRITC and sheep-anti-chicken-TRITC) were from Nordic Labs. Both first and second layers were titrated and used at saturating condition with no detectable nonspecific staining (see details in ref. 8).

‡In the fetal thymus the few TdT⁺ cells stain extremely weakly. These cells are small HLA-A,B⁻, HTA-1⁺ thymocytes¹⁷.

§Some of these samples were tested 2 d after being obtained; the E⁺ values could therefore be artificially low.

||Weak staining.

of the fact that a variable proportion of the blast cells also expressed HTA-1.

As there was a marked discrepancy between the staining pattern of infant thymocytes and Thy-ALL blasts, we have investigated normal fetal thymocytes. The possibility that Thy-ALL might derive from fetal thymocytes has been raised by Gatten *et al.*¹³ and Stein *et al.*⁷ who showed that these cell types, unlike mature cortical thymocytes, carry receptors for activated C3 and form EAC rosettes. Nevertheless, in the three fetal thymus samples (at 14, 17 and 19 gestational weeks) simultaneously analysed for nuclear TdT and membrane HLA-A, -B and -C expression no cells expressed both markers. The vast majority of cells (90–95%, including most HTA-1⁺ cells) were TdT⁻. These results were in accord with the low or undetectable TdT values observed in the same fetal human thymus samples by the biochemical assay (G. J., K. Ganeshaguru and A. V. Hoffbrand, unpublished observation) and with observations in chicken¹⁴, mice and rats¹⁵, which also showed that fetal thymocytes are TdT⁻.

In the final part of the study we postulated that perhaps Thy-ALL blast cells express the phenotypic characteristics of rare bone marrow (BM) cells. BM samples from 5–12-year-old children with no haematological malignancy were analysed with various double markers. The phenotypes of these TdT⁺ BM cells were, again, different from that of both Thy-ALL blasts and thymocytes. Unlike thymocytes and Thy-ALL blasts, BM TdT⁺ cells failed to express HuTLA and HTA-1 (Fig. 2; see also ref. 5). All TdT⁺ BM cells (>99%) were brightly stained for HLA-A, -B, and -C; and the vast majority (>85%) were also brightly stained for Ia-like antigens (Ia⁺). This agrees with previous results⁵, suggesting that the phenotypic characteristics of TdT⁺ BM cells were similar to the phenotype of cALL blasts and different from those of Thy-ALL blasts.

In conclusion, our results indicate that human leukaemic blasts and cell lines of Thy-ALL phenotype (HuTLA⁺, E⁺, Ia⁻, HTA-1⁺) have an unexpected expression of HLA-A, -B, and -C antigens when compared to small cortical thymocytes or putative large TdT⁺ thymic prothymocytes. There are at least three possible interpretations of our findings. It is possible that even the sensitive single cell assays used are unable to detect TdT⁺,

brightly HuTLA⁺, HLA-A, -B and -C⁺, Ia⁻ bone marrow precursor cells (possibly bone marrow prothymocyte) from which Thy-ALL might develop because these cells are exceedingly rare (<10⁻⁴). It is also conceivable that the generation of HLA-A, -B and -C antigens on cortical thymocytes is associated with the malignant change (for example the rare HLA-A, -B, and -C⁺ thymic cells might be predisposed to undergo a malignant transformation) and therefore most Thy-ALL show this peculiar phenotype. It seems more likely, however, that within the intact thymic cortex microenvironmental effects modulate (that is, they actively suppress) the expression of HLA-A, -B and -C antigens on normal cortical thymocytes as part of the physiological interplay between epithelial and lymphoid elements. This possibility is in line with the experimental observations that only during this special cortical development stage do T-lineage cells lack the easily detectable HLA, -B and -C antigens^{16,17}. Thus, although Thy-ALL blasts may have originated from a thymic precursor cell (HuTLA⁺, TdT⁺, Ia⁻), they exhibit HLA-A, -B and -C antigens perhaps due to the loss of thymic microenvironmental control during the disseminated phase of the disease.

We thank Dr P. Beverley (ICRF Human Tumour Immunology Unit, University College Hospital, London) for 2D1 antibody.

Nonsteroidal compounds which bind epididymal androgen-binding protein but not the androgen receptor

Guy G. Rousseau*, Jacques I. Quivy & Josef Kirchhoff†

International Institute of Cellular and Molecular Pathology, ICP 7529, 75 avenue Hippocrate, B-1200 Brussels, Belgium

Xuân-Hoa Bui & Raymond Devis

Unité de Chimie Hormonologique et de Pharmacognosie (CHHP), Université de Louvain, 54 avenue Hippocrate, B-1200 Brussels, Belgium

In the testis of most mammals the Sertoli cells of the seminiferous tubules secrete into the lumen an androgen-binding protein (ABP). This glycoprotein is of interest because it reflects Sertoli cell function and responsiveness to follicle-stimulating hormone¹. In addition, ABP binds testosterone produced by the Leydig cells and the hormone-protein complex reaches the epididymis² where it could play a role in sperm maturation³⁻⁶. ABP is distinct from the androgen receptor, an intracellular protein which binds testosterone and its hormonally active metabolite 5 α -dihydrotestosterone (DHT) in target tissues⁷. In some species, but not the rat, a testosterone-oestradiol binding globulin (TeBG) circulates in blood⁸. Although radioimmunoassays for TeBG⁹ and ABP¹⁰ have been developed, most methods for assaying these proteins and the androgen receptor rely on their ability to bind ³H-labelled androgens. As all three proteins bind testosterone and DHT, accurate assay of any one protein awaits development of a specific label. A specific ligand for ABP would also be very valuable for further study of the physiologic role of ABP. We¹¹ and others¹² have investigated earlier suggestions² that the binding sites on ABP and the androgen receptor have different steroid specificities. Steroids were found that have a higher affinity for ABP than for the receptor. We now report on dicyclohexane derivatives which bind with high affinity to the testosterone-binding site on ABP but do not interact with the androgen receptor.

The dicyclohexane derivatives shown in Table 1 were synthesised by catalytic perhydrogenation of diethylstilboestrol (III, V) or of mesohexestrol (IV). Chromic oxidation of these diols yielded the corresponding diketones (I, II). All compounds were purified and characterised as part of a project on the androgenic activity of nonsteroidal molecules¹³. We first studied their effect on the interaction of androgens with ABP from rat epididymis. Specific binding was determined by a charcoal adsorption assay which we have shown to give results identical to those obtained by the classical procedure of steady-state polyacrylamide gel electrophoresis¹¹. As illustrated in Fig. 1a, compounds I, II and III could inhibit completely the binding of DHT to ABP. This effect appeared to be specific since compounds IV and V at a 2,000-fold excess produced less than 20% inhibition. The question of whether the inhibition was competitive or not was then investigated. ABP binding of DHT was studied at increasing concentrations of the latter in the presence of fixed concentrations of the analogues. Lineweaver-Burk plots of data obtained at equilibrium confirmed that DHT interacts with a single class of sites as demonstrated earlier by Scatchard analysis¹¹ and suggested that the nonsteroidal compounds interfere with DHT binding by competitive inhibition (Fig. 1b). The equilibrium affinity constants calculated from these plots are listed in Table 1. In other experiments, 1 μ M nonradioactive DHT or compound I was added to preformed

³H-labelled DHT-ABP complex. In both cases, binding was completely reversible; the time-dependent decrease in specifically-bound radioactivity followed the same first-order kinetics (half life 5.8 min) with compound I as with DHT. Thus, the properties of the binding site for the natural androgen were not modified by the presence of compound I.

The effect of the dicyclohexane derivatives on the binding of androgens to their intracellular receptor protein was quite different. Cytosol from rat ventral prostate was incubated with ³H-labelled methyltrienolone (RU 1881), a specific ligand for the androgen receptor¹⁴. In conditions where testosterone and

Fig. 1 Binding of dicyclohexane derivatives to ABP (closed symbols) and to the androgen receptor (open symbols). Epididymes and ventral prostates obtained from Wistar rats 24 h after castration were homogenised at 0 °C in 20 mM Tris-HCl buffer (pH 7.4) containing 1.5 mM EDTA and 10% (v/v) glycerol without (epididymis) or with (prostate) 0.25 mM dithiothreitol. Homogenates were centrifuged at 200,000g for 60 min at 0 °C to yield the cytosol. Androgen receptor in epididymis cytosol was inactivated by freezing (-20 °C) and thawing (30 °C, 30 min) in the absence of dithiothreitol, conditions to which ABP is insensitive¹¹. *a*, Epididymis cytosol was incubated for 3 h with 1.5 nM ³H-DHT in the presence of the indicated concentrations of inhibitors (see Table 1 for nomenclature) and specific binding to ABP was determined as described¹¹. Briefly, unbound hormone was removed from the 0.4 ml incubation mixtures by adding 0.2 ml of activated charcoal suspension (Norit A 50 mg ml⁻¹, dextran 5 mg ml⁻¹) and sedimenting the charcoal after 2 s of agitation. Nonspecific binding was calculated from parallel incubations containing a 500-fold excess of nonradioactive DHT. Prostate cytosol was incubated with 2.5 nM ³H-methyltrienolone for 16 h for determination of binding to the androgen receptor¹¹, in absence or presence of the inhibitors. Specific binding is expressed as a percentage of maximum binding seen in the absence of inhibitors (7,100 d.p.m. per ABP assay and 7,340 d.p.m. per receptor assay). Nonspecific binding was 10 and 27% of total binding for ABP and the receptor, respectively. *b*, Double-reciprocal plot of ABP binding at increasing ³H-DHT concentrations in the absence or presence (1 μ M) of inhibitor.

† Present address: Institut für Physiologische Chemie, D-4300 Essen, 1, FRG.

DHT completely inhibited methyltrienolone binding, none of the compounds except II had any effect. Compound II displayed some inhibition at high concentrations (Fig. 1a). From double-reciprocal plots, this inhibition was found to be competitive.

Thus, compounds I and III specifically bind to ABP but not to the androgen receptor. Androgens are known to bind to the glucocorticoid receptor, in which system they behave as antagonists¹⁵. However, none of the nonsteroidal compounds bound to the glucocorticoid receptor from rat hepatoma cells. Unlike diethylstilboestrol from which it is derived compound I, which has the highest affinity for ABP, did not bind to the oestrogen receptor from rat uterus.

Since ABP has many characteristics in common with TeBG¹⁶, we wondered whether the nonsteroidal compounds also bound to TeBG. As this protein is not found in the rat, the test was performed on human TeBG. Human male plasma was diluted 10-fold with 20 mM Tris-HCl, 1.5 mM EDTA, 10% (v/v) glycerol, pH 7.4 and agitated for 45 min at room temperature with 1% (w/v) activated charcoal to remove endogenous steroids. After centrifugation the supernatant was incubated with 5 nM ³H-labelled DHT for 3 h without or with 10 μ M nonradioactive DHT and specific binding was determined as described for ABP. A 2,000-fold excess of compound III was required for inhibition of the binding of DHT to TeBG by 30%.

Table 1 Dicyclohexane derivatives studied

Compound			Diastereo-isomerism at C-1,1'	K_a (M ⁻¹)
	R ₁	R ₂		
I	= 0	= 0	Racemic	12.0×10^6
II	= 0	= 0	Meso	4.8×10^6
III	e OH, a H	a OH, e H	Racemic	3.5×10^6
IV	e OH, a H	e OH, a H	Meso	0.8×10^6
V	e OH, a H	e OH, a H	Racemic	0.6×10^6

e, equatorial; a, axial (see ref. 13). K_a is the equilibrium association constant (0 °C) for rat ABP calculated for double-reciprocal plots as in Fig. 1.

In these conditions, the other compounds had no effect while, as expected, oestradiol completely inhibited DHT binding to TeBG. Thus, in our assay systems, compound I bound strongly to ABP but not to TeBG nor to the androgen receptor. These results, however, do not allow immediate predictions concerning binding of the nonsteroidal analogues to the controversial¹⁷⁻²⁰ human ABP as it is known that ABPs from different species differ in steroid specificity²¹.

The data presented here confirm that the androgen-binding sites on ABP and the androgen receptor have different specificities. We have found dicyclohexane derivatives which display an absolute specificity for ABP when tested in parallel for androgen receptor binding. Steroidal and nonsteroidal ligands which specifically inhibit binding of androgens to ABP may be of interest for studying regulation of male fertility.

High-affinity binding of ¹²⁵I-labelled mouse interferon to a specific cell surface receptor

Michel Aguet

Laboratory of Viral Oncology, Institut de Recherches Scientifiques sur le Cancer, BP8, 94800 Villejuif, France

Previous research suggests that interferon binds to the cell surface¹, possibly by attachment to gangliosides^{2,3}. A two-component receptor system consisting of binding and activation sites has been proposed⁴. This hypothesis is supported by the finding that interferon inhibits binding of cholera toxin and thyrotropin to their receptors^{5,6} suggesting possible common receptor sites. Moreover, an antiserum against cell surface components of interferon-sensitive cells has been shown to inhibit the action of interferon⁷. However, to understand the interaction of interferon with the cell surface requires direct ligand-binding studies. I present here direct evidence that high-affinity binding of interferon to a specific cell surface receptor is an initial step in interferon action using biologically active purified ¹²⁵I-labelled mouse interferon. Labelled interferon binds specifically to interferon-sensitive mouse leukaemia L1210 cells, whereas binding to interferon-resistant L1210 cells is nonspecific. Furthermore, specific binding to monolayer cultures of mouse L929 cells is compared with nonspecific binding to chick embryo fibroblasts insensitive to the action of mouse interferon⁸.

Partially purified mouse C243 cell interferon⁹ was further purified by affinity chromatography on a sheep-anti-mouse interferon antibody agarose column as previously described^{10,11}, followed by ion exchange chromatography on CM-Sepharose CL-6B (Pharmacia). This procedure yielded highly purified interferon with a specific activity of 5×10^8 - 10^9 mouse interferon reference units per mg of protein with a recovery of 50-75% (Fig. 1a). Interferon was assayed on mouse L929 cells challenged with vesicular stomatitis virus as described previously¹⁴; protein concentrations were estimated according to the method of Lowry.

Purified interferon was iodinated with ¹²⁵I to a specific radioactivity of 70-80 μ Ci per μ g of protein using a modified lactoperoxidase-catalysed reaction¹⁵; monoiodination of a protein with a molecular weight (MW) of 35,000 should result in a specific activity of 57 μ Ci per μ g of protein. Labelled interferon was reduced with 1% 2-mercaptoethanol in 0.1% SDS; this procedure allowed recovery of 25-50% of the initial biological activity, whereas the recovery was less than 20% before reduction, in agreement with similar previously reported results (ref. 16, Fig. 1b, c). Control experiments performed with cold iodine,

Fig. 1 SDS-polyacrylamide gel electrophoresis (SDS-PAGE) was performed according to the method of Laemmli¹². Homogeneous slab gels of 12.5% acrylamide, 0.8 mm thick, 90 mm long and 130 mm wide were overlaid with a 10 mm long 3% stacking gel and run with a constant current of 10 mA in presence of 0.1% SDS (BDH). The samples were dialysed against 0.125 M Tris-HCl (pH 6.8) containing 1% SDS and heated for 2 min in a boiling water bath after addition of 1% 2-mercaptoethanol (Eastman). The sample size was 25 μ l. *a*, Coomassie blue staining of purified interferon. After elution from 2 mm gel slices, antiviral activity was associated with all three bands which correspond to apparent MWs of 35,000, 28,000 and 22,000. This interferon therefore appears to be electrophoretically similar to a recently described purified interferon prepared from Newcastle-disease-virus infected mouse Ehrlich ascites tumour cells¹³. *b*, Profile of radioactivity of ¹²⁵I-labelled purified interferon. The fractions correspond to gel slices of 2 mm. *c*, Profile of eluted antiviral activity from the material depicted in *b*. The profile is congruent with the radioactivity peaks at MWs of 35,000 and 28,000; however no antiviral activity was detectable at MW 22,000. Molecular weight markers (Sigma) were bovine serum albumin (66,000), egg albumen (45,000), trypsinogen (24,000), beta-lactoglobulin (18,400) and lysozyme (14,300). *d*, Profile of radioactivity of bound and eluted ¹²⁵I-interferon from L1210-S (●) and L1210-R (○) cells.

Fig. 2 The continuous cell lines of L1210-S and L1210-R cells were grown in non-agitated suspension cultures in RPMI 1640 medium (Flow laboratories) supplemented with 10% fetal calf serum (Gibco Bio-Cult)¹⁹. Cells (2×10^6) were incubated with ¹²⁵I-interferon in 24-well Costar 3524 plates at a density of 2×10^6 cells per ml and subsequently washed three times with culture medium by centrifugation at 4 °C. All experiments were performed in triplicate. The radioactivity was measured in a Gammatic gamma counter. *a*, Time-course of ¹²⁵I-interferon binding to L1210-S (●) and L1210-R (○) cells at a concentration of 400 U ml⁻¹ at 37 °C. Simultaneous addition of 4×10^5 U ml⁻¹ of unlabelled interferon inhibits binding to L1210-S (▲) cells, whereas binding to L1210-R (△) cells is unaltered; *b*, time course of binding at 4 °C. Standard deviations were less than 5%.

or omitting iodine in otherwise identical labelling conditions, suggest that the irreversible inactivation on iodination is due either to conformational changes as a consequence of substitution or to iodine-induced irreversible oxidation reactions.

Mouse leukaemia L1210 cells have been characterised extensively in terms of sensitivity to the various biological effects of interferon^{17,18}. An interferon-resistant subline of these cells has been cloned and the resistance to the different effects of interferon is well documented¹⁹. The time-course of ¹²⁵I-interferon binding to both cell lines is shown in Fig. 2: binding to interferon-sensitive L1210 cells (L1210-S) occurred rapidly and progressively and could be competitively inhibited by simultaneous addition of an excess of unlabelled interferon. Binding to interferon-resistant L1210 cells (L1210-R) was minimal and independent of the addition of unlabelled ligand. This binding can therefore be referred to as nonspecific. These findings confirm previous experiments on the recovery of antiviral activity from L1210-S cells, but not from L1210-R cells on treatment with large amounts of interferon¹⁹. While maximum specific binding was achieved after 120 min independently of temperature, the amount of specifically bound material was markedly higher at 37 °C than at 4 °C. We are now investigating whether this increased binding at 37 °C reflects a continuous uptake of interferon, as has been suggested previously²⁰.

The saturation of specific receptor sites for interferon is depicted in Fig. 3. Binding of ¹²⁵I-interferon to L1210-R cells as

a function of the concentration of added labelled ligand was linear and thus nonspecific; no saturation occurred in the range of biologically active concentrations. The specific receptor sites on L1210-S cells, however, were saturated between interferon concentrations of 3,200 and 6,400 units per ml, at 37 °C as well as at 4 °C (data not shown). Thus the saturation curve is congruent with the biological dose-response curve reported previously²¹.

To characterise this bound fraction further, L1210-S cells were incubated for 120 min with 6,400 units per ml of labelled interferon in the cold, washed and subsequently incubated with a 2,000-fold excess of unlabelled interferon for another 2 h at 4 °C. In these conditions 70% of the bound radioactive material was recovered, compared to less than 25% spontaneously released material. On analysis by SDS-PAGE the radioactivity profile of the specifically bound and eluted material corresponds to the profile of antiviral activity of the original ¹²⁵I-interferon preparation (Fig. 1c, d). Control experiments in which ¹²⁵I-interferon was bound and eluted from L1210-R cells confirmed the nonspecific binding to these cells (Fig. 1d).

The comparison of binding of ¹²⁵I-labelled mouse interferon to interferon-sensitive mouse monolayer L929 cells with binding to chick embryo fibroblasts, insensitive to mouse interferon⁸, yielded similar results to those obtained with L1210-S and L1210-R cells (data not shown). In contrast to the specific binding to mouse L929 cells binding of ¹²⁵I-labelled mouse interferon to chick embryo fibroblasts could not be inhibited competitively by simultaneous addition of an excess of unlabelled mouse interferon. Specific binding to mouse L929 cells revealed saturation at a concentration of 6,400 units per ml interferon and can thus be expected to occur with a similar high affinity as on L1210-S cells; however, chick embryo fibroblasts could not be saturated with ¹²⁵I-labelled mouse interferon in the same range of concentrations. Binding of mouse interferon to chick embryo fibroblasts could thus be characterised as nonspecific, in agreement with the observation that interferon can be recovered from homologous, but not from heterologous cells previously treated with high amounts of interferon²².

The various approaches for the characterisation of the specific interaction between high affinity membrane receptors and their ligands has been the subject of reviews by Kahn²³ and Cuatrecasas²⁴. The mass action law can serve as a model for the interaction of a ligand with its receptor on the assumption that the binding corresponds to a simple bimolecular equilibrium. It can be derived from the equation of mass action law, that the dissociation constant at half saturation of the receptor sites is equal to the concentration of free ligand at half saturation. As less than 10% of the added labelled interferon was bound to the cells at half saturation, the concentration of free ligand can be set equal to the known total ligand concentration. Assuming that labelled interferon possesses identical binding properties as the unlabelled material and that only biologically active labelled interferon binds specifically, an apparent affinity constant for binding of interferon to L1210-S cells can be derived from the saturation curve depicted in Fig. 3: half saturation is achieved at a concentration of 400–800 units per ml, equivalent to $1-2 \times 10^{-11}$ M for a mean MW of 35,000 and a specific activity of 10^9 units per mg protein.

Fig. 3 Saturation of ¹²⁵I-interferon binding to L1210-S (●) and L1210-R (○) cells after 2 h incubation at 37 °C. The specific binding is depicted as the difference between total binding to L1210-S cells and nonspecific binding to L1210-R cells (dotted line). Standard deviations were less than 5%.

The present results provide, for the first time, direct evidence for high affinity binding to a specific cell surface receptor as the initial step in interferon action. Thus interferon binding shares a characteristic property of other biologically highly active substances such as peptide hormones and neurotransmitters²³. This strongly suggests that the mechanism of resistance to interferon across the barrier of species specificity, as well as the resistance of L1210-R cells is located at the cell surface. Ligand binding studies offer new possibilities for a direct approach to the study of several aspects of interferon action. Thus interferon antagonists, interferon derivatives or heterologous interferons may be analysed directly with regard to competitive binding and biological crossreactivity. Furthermore, use of biologically active, purified ¹²⁵I-interferon offers new possibilities to investigate binding and pharmacokinetic properties *in vivo*.

I thank Dr I. Gresser for encouragement and help, as well as for reviewing the manuscript, Dr R. Monier for his interest and suggestions, Drs M. Tovey and E. Mogensen for helpful discussions and Mrs B. Blanchard for technical assistance. This work was partly supported by grants from DRET (78-34-210), DGRST (79-7-0205) and INSERM (ATP 78-90). M.A. was supported by a Postdoctoral Fellowship from the Swiss NSF.

Protein kinase in immunoprecipitate of DMBA-transformed epithelial cells with serum from tumour-bearing rabbits

Ian Summerhayes & Lan Bo Chen

Sidney Farber Cancer Institute and Department of Pathology, Harvard Medical School, Boston, Massachusetts 02115

Recent work using virally transformed cells has shown that the viral gene product responsible for transformation is associated with protein kinase activity^{1,2}. Use of antisera specific for the *src* gene product of Rous sarcoma virus showed that the heavy chain of the antibody in the immunoprecipitate can be phosphorylated by the bound antigen *src* gene product. Only a very low level of such protein kinase activity was observed using uninfected cells or cells infected with transformation-defective virus. Such a low level of activity has been attributed to the endogenous *src* gene product^{3,4}. Similar protein kinase activity, capable of phosphorylating IgG, was also detected in the immunoprecipitate of the T antigen of adenovirus type 5 (ref. 5). Moreover, large T antigen of SV40 is also associated with protein kinase and/or ATPase activity^{6,7}. Thus, many of the virally coded proteins involved in transformation are apparently associated with protein kinase activity. In addition, secretion of specific phosphoproteins and increased protein kinase activity have been detected in conditioned medium from cells transformed by oncogenic viruses⁸. Secretion of these proteins, accompanied by an additional protein kinase, correlates well with the transformation as demonstrated by the use of temperature-sensitive mutants in the *src* gene of avian sarcoma virus. These data suggest that the alteration in protein phosphorylation may contribute to the transformed state. In the virion of murine sarcoma virus but not murine leukaemia virus, a novel protein kinase with molecular weight of 15,000 (15 K) has recently been discovered⁹. In view of these findings, it is of interest to investigate whether in chemical carcinogen transformed epithelial cell an analogous event also occurs. We studied transformed bladder epithelial cells induced after *in vitro* exposure to the chemical carcinogen, 7,12-dimethylbenz[*a*]anthracene (DMBA). Anti-serum against DMBA-transformed mouse bladder epithelial cells were raised in rabbits and used to immunoprecipitate antigens from chemically transformed cell lysates. By incubating the immune complex with [γ -³²P]ATP we found that a transformation-specific 18K protein becomes phosphorylated. Such a phosphorylatable 18K protein is also detected in the conditioned medium of DMBA-transformed cells.

Background work on the establishment, characterisation and tumorigenicity of the DMBA-transformed bladder epithelial cell lines has been published previously¹⁰. Tumours were induced by subcutaneous injection of DMBA-transformed mouse bladder epithelial cells ($1-2 \times 10^6$ cells) into 5-week old New Zealand rabbits. Three more weekly injections of the same cell line into the same site were given. One week after the last injection, blood was collected. Of the five antisera raised against different epithelial cell lines, immunoprecipitates from four gave identical results in the phosphorylation of an 18K protein. One of them, raised against MB49 and designated serum V, was used in this study because of its higher titre.

Cytoplasmic extracts prepared from cultures of primary cells, untransformed cell lines and chemically transformed epithelial cells, were immunoprecipitated with immune or non-immune serum on protein A-Sepharose beads. Extensively washed immunoprecipitates were then incubated with [γ -³²P]ATP, rewashed and analysed by SDS polyacrylamide gel electrophoresis. Figure 1e shows an immunoprecipitate of a DMBA-transformed epithelial cell line with phosphorylation of an 18K

protein which could sometimes be resolved as a doublet. Similar results were observed when the immunoprecipitate was made to a benzo[*a*]pyrene (BP) transformed rabbit bladder epithelial cell line. Non-immune serum (Fig. 1c,f) and a variety of other antisera against fibronectin, p60^{src}, FOCMA, SV40-T antigen and polyoma-T antigen, did not support a phosphotransfer reaction in the immunoprecipitate of the DMBA-transformed epithelial cells. We also failed to detect ³²PO₄-labelled 18K proteins in immunoprecipitates of immune serum V reacted with primary cultures of epithelial cells, fibroblasts and endothelial cells (Fig. 1h, i, j respectively). However, among a variety of established cell lines tested, the phosphorylation of the 18K protein was detected in immunoprecipitates of mouse BALB 3T3-A31 cells and CCL146 (gerbil fibroma) cells with immune serum V (Fig. 1b). In other established cell lines (Rat 1 and NRK) scored negative for protein kinase (Table 1), small amounts of radioactive incorporation in the 18K region could be detected (Fig. 1g) after prolonged exposure of the gel. Cell lines which failed to react with serum V to give the 18K protein included RK13 (rabbit kidney), CCL60 (rabbit fibroblast), CV-1 (monkey kidney) and RPL (rat liver). For virally transformed cells tested, no detectable phosphorylatable 18K was observed in immunoprecipitates with immune serum V in these experimental conditions. These include RSV-chick, RSV-rat (CCL47), SV80 (SV40 human cells), 64F3 (FeSV-CCL64) and T8 (adenovirus types 2 transformed rat cells). It should also be noted that the incubation of [γ -³²P]ATP with the immunoprecipitate of the *src* gene product of RSV or the T antigen of SV40 or polyoma virus does not result in the appearance of ³²P-labelled 18K protein.

When immune serum V was incubated with formaldehyde-fixed DMBA-transformed epithelial cells (MB49), and then

Table 1 Protein kinase activity in immunoprecipitates of different cell types with tumour-bearing serum

Cell types		Relative amount of ³² PO ₄ -labelled 18K protein, % of MB ₄₉
<i>Primary cultures</i>		
(1) Embryo fibroblasts	rat	0
(2) Embryo fibroblasts	chick	0
(3) Embryo fibroblasts	Chinese hamster	0
(4) Bladder epithelium	mouse	0
(5) Bladder epithelium	rabbit	0
(6) Aorta endothelium	cow	0
<i>Spontaneous cell lines</i>		
(1) CV-1	Monkey	0
(2) NRK	rat	5%
(3) Rat 1	rat	2%
(4) RPL	rat	0
(5) RK13	rabbit	0
(6) CCL 60	rabbit	0
(7) BALB 3T3-A31	mouse	80%
<i>Chemically transformed epithelial cell lines</i>		
(1) MB33 I	mouse-DMBA	100%
(2) MB33 II	mouse-DMBA	100%
(3) MB48 B	mouse-DMBA	100%
(4) MB49	mouse-DMBA	100%
(5) MB49 B	mouse-DMBA	100%
(6) MB63	mouse-DMBA	100%
(7) MB71 B	mouse-DMBA	100%
(8) RBC	rabbit-benzo[<i>a</i>]pyrene	100%
<i>Tumour-derived cell lines</i>		
(1) CCL146	gerbil-fibroma	100%
(2) B103	rat-neuronal tumour	0
<i>Virally transformed cell lines</i>		
(1) CCL47	rat-RSV	0
(2) 64F3	mink-FeSV	0
(3) SV80	human-SV40	0
(4) CEF/Ts68	chick-RSV	0
(5) T8	rat-adenovirus 2	0

used to immunoprecipitate antigens for chemically transformed cell lysates, phosphorylation of the 18K protein was greatly reduced (Fig. 1a, d). Removal of such activity can also be accomplished by incubation of antiserum with live DMBA-transformed cells. However, absorption of tumour-bearing serum V on fixed primary epithelial cells or cells scored negative for the phosphorylated 18K protein does not result in the reduction of phosphorylation activity after immunoprecipitation. Thus, it is reasonable to conclude that the phosphorylation activity observed in immunoprecipitate is induced after oncogenic transformation by the chemical carcinogen.

Antiserum V, although raised in the rabbit by injecting mouse cells, is not species specific. It recognises an 18K protein in mouse, rat, rabbit and gerbil cell lines. As summarised in Table 1, this 18K protein seems to be transformation-dependent. As the ^{32}P -labelled 18K protein is not detectable in immunoprecipitates of serum V with a variety of virally transformed cells, this protein is probably not a common transformation-dependent protein. Rather, it seems to be confined to only chemically transformed cells and a few immortal cell lines.

Fig. 1 Detection of a protein kinase activity in immunoprecipitates of various cell types. Cytoplasmic extracts were prepared and immunoprecipitated with tumour-bearing rabbit serum V, serum V absorbed with formaldehyde fixed DMBA-transformed mouse epithelial cells, MB49, or non-immune serum. Cells (2×10^6) were washed five times with STE buffer (0.15 M NaCl/0.1 M Tris-HCl, pH 7.2/0.001 M EDTA) and lysed in 0.7 ml of RIPA buffer (1.0% Triton X-100/1.0% sodium deoxycholate/0.1% SDS/0.15 M NaCl/0.01 M Tris-HCl, pH 7.2) supplemented with 200 units ml^{-1} of Trasylol (Calbiochem) at 4°C . Cell lysate (0.5 ml) was mixed with 10 μl of non-immune serum and 40 μl of protein A Sepharose CL-4B (Pharmacia). After 10 min of gentle agitation the mixture was centrifuged at 28,000g for 30 min and the supernatant was removed for immunoprecipitation. To 100 μl aliquots of supernatant 10 μl of immune serum 40 μl of protein A-Sepharose was added and incubated at 4°C for 30 min with constant mixing. The immune complexes were washed four times with RIPA buffer and then once with phosphate-buffered saline (PBS). The pellet was incubated at room temperature for 20 min in a buffer containing 0.1 M Tris, pH 7.4; 1 mM MgCl_2 and $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ (0.1 μM , specific activity 2000 Ci mmol^{-1} ; NEN) and then washed four times with PBS to remove unbound radioactivity. The immune complexes were eluted from the Sepharose beads by boiling in buffer containing 1% SDS and 2% β -mercaptoethanol for 4 min. The supernatant was then analysed by SDS polyacrylamide (12.5%) slab gel. The gel was stained with Coomassie brilliant blue, dried and an autoradiograph was prepared by Kodak SB-5 film. Cell line derived from gerbil benign tumour, CCL146 with a, absorbed serum V; b, serum V; c, non-immune serum. DMBA-transformed mouse bladder epithelial cell line MB49 with d, absorbed serum V; e, serum V; f, non-immune serum; g, NRK with serum V. Primary cultures with serum V, h, mouse bladder epithelium; i, hamster embryo fibroblasts; j, bovine endothelial cells. The molecular weight markers used were myosin heavy chain (200K), tubulin (52K), troponin T (36K) and lactoglobulin (18K).

Fig. 2 Protein kinase in immunoprecipitates of conditioned medium from normal and chemically transformed cells. Conditioned medium immunoprecipitated with serum V, was incubated for 20 min with $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ at room temperature. Immune complexes were eluted from Sepharose beads and analysed on an SDS polyacrylamide slab gel. Conditioned medium from a, DMBA-transformed epithelial cell line, MB49; b, primary culture of mouse bladder epithelium. The molecular weight markers used are myosin heavy chain (200K), tubulin (52K), troponin T (36K) and lactoglobulin (18K).

Serum-free medium was conditioned for 24 h with MB49 cells, collected from the dish and centrifuged to clear it of any cells. The conditioned medium was either incubated with $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ for 20 min and then immunoprecipitated with serum V or immunoprecipitated first and then incubated with $[\gamma\text{-}^{32}\text{P}]\text{ATP}$. Both procedures resulted in the detection of ^{32}P -labelled 18K protein from DMBA-transformed cells (Fig. 2a) but not primary epithelial cells (Fig. 2b). The phosphorylation of an 18K protein in conditioned medium was destroyed when conditioned medium was first heated to 100°C for 1 min before incubation with $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ but was unaffected by heat treatment at 56°C for 30 min.

Fig. 3 SDS polyacrylamide gel analysis of immunoprecipitate of ^{35}S -methionine or ^{32}P -phosphate labelled conditioned medium from DMBA-transformed epithelial cell line, MB49, with tumour-bearing serum V. Confluent cells were incubated with ^{35}S -methionine (NEN, 400 Ci mmol^{-1} , 75 $\mu\text{Ci ml}^{-1}$) or ^{32}P -phosphate (NEN, 2,000 Ci mmol^{-1} , 200 $\mu\text{Ci ml}^{-1}$) in Dulbecco-modified Eagle's medium deficient in methionine or phosphate for 24 h. After centrifugation at 100g for 10 min, the supernatant was used for immunoprecipitation a, ^{35}S -methionine labelled, non-immune serum; b, ^{35}S -methionine labelled, tumour-bearing serum; c, ^{32}P -phosphate labelled, non-immune serum; d, ^{32}P -phosphate labelled, tumour-bearing serum. The molecular weight markers used were myosin heavy chain (200K), vimentin (58K), egg albumin (42K) and lactoglobulin (18K).

Evidence that the 18K protein is synthesised by cells and not acquired from serum was demonstrated by the incorporation of ^{35}S -methionine and ^{32}P -phosphate into 18K protein (Fig. 3) and the fact that in the absence of serum, cells continued to synthesise this protein and shed it into the culture medium.

Phosphorylation of the 18K protein, in immunoprecipitates of cell lysate or conditioned medium, was neither cyclic AMP nor cyclic GMP dependent. The reaction required a proper concentration of Mg^{2+} (1 mM) and was not inhibited by Ca^{2+} (1–10 mM). Intriguingly, it was inhibited by F-actin, similar to that of protein kinase associated with the *src* gene product¹¹ or with murine sarcoma virus⁹. Both ATP and GTP can be utilised for the phosphotransfer reaction. In many respects, the profile of phosphorylation of the 18K protein is similar to the phosphorylation of IgG heavy chain in the immunoprecipitate of *src* gene product.

The presence of a transformation-associated protein kinase activity reported in this study is similar, conceptually, to that reported for virally transformed cells^{1,2} but differs with respect to the substrate phosphorylated in similar experimental conditions. Serum directed against p60^{src}, the product of the *src* gene

of avian sarcoma virus, does not immunoprecipitate any detectable kinase activity from DMBA-transformed cells and conversely, immunoprecipitates of serum V with virally transformed cells does not result in the phosphorylation of the heavy chain of IgG on addition of $[\gamma\text{-}^{32}\text{P}]\text{ATP}$. Since alteration of protein phosphorylation plays an important part in several biological processes^{12–14}, the difference found between normal and chemically transformed cells in this respect may be of significance to the understanding of transformation induced by chemical carcinogens.

The possibility that our transformation-associated phosphoprotein may have growth-promoting properties¹⁵, protease activity¹⁶ or angiogenesis activity¹⁷ are currently under investigation. The isolation of the 18K phosphoprotein should help identify its biochemical role and clarify as to whether the expression and secretion of this protein is a causative or secondary event in transformation induced by chemical carcinogens such as DMBA or BP.

We thank Beth Shepherd and Rebecca Reynold for technical assistance. This work was supported by a grant from National Cancer Institute (P01CA22427-02).

The secretion of aldosterone from the zona glomerulosa of the mammalian adrenal cortex is stimulated by ACTH, potassium, angiotensin II and III, growth hormone, serotonin and E series prostaglandins^{1–7}. Some experimental and clinical studies suggest that additional stimulants of the zona glomerulosa must exist, possibly including pituitary factors other than ACTH^{6,8–13}. The possibility that posterior pituitary extracts may contain a zona glomerulosa stimulant was first suggested 20 years ago^{14,15}, but has since received little attention. We describe here the purification from posterior pituitary extracts of activities that stimulate rat glomerulosa cells and whole tissue *in vitro*. One of the active compounds has been identified as α -MSH (melanocyte stimulating hormone).

Two posterior pituitary extracts were investigated, one an extract of bovine posterior pituitaries¹⁶, the other Pitressin (Parke Davis). Their effects on the production of corticosterone by adrenal cell suspensions compared to ACTH are shown in Table 1. Values obtained for the stimulation by ACTH are

consistent with those obtained previously in these laboratories, and also with those reported by other workers^{1,17,18}. Posterior pituitary extract 1 also stimulated both glomerulosa and inner zone adrenal cells, but the dose required to give half-maximal stimulation is lower than expected on the basis of immunoassayable ACTH by a factor of about 17 for glomerulosa cells based on the C-terminal assay¹⁹, but only 6.6 for the N-terminal assay¹⁹, and of about 10 and 3 respectively for fasciculata/reticularis cells. Pitressin stimulates glomerulosa cells alone and has no effect on inner zone cells. Neither vasopressin, substance P nor neurotensin have any effect on either cell type in the conditions used.

For bioassay purposes, the production of corticosterone alone was used as a measure of steroidogenesis. However, the effect of the stimulators on the total steroid profile of the glomerulosa using whole tissue preparations is shown in Fig. 1. It can be seen

Table 1 Potencies of various stimulants on rat adrenocortical cell suspensions

	ACTH (mol l ⁻¹)	Posterior pituitary extract no. 1 (μg)	Pitressin (pressor units)
Glomerulosa cells	6.6×10^{-11}	13.7 (4×10^{-12} C-terminal; 4×10^{-11} N-terminal)	108 mU
Fasciculata/ reticularis cells	6.9×10^{-11}	20 (6×10^{-12} C-terminal; 1.5×10^{-11} N-terminal)	NS

Values are amounts of stimulant which in standard incubation conditions give half maximal stimulation of corticosterone production. Units are: ACTH, mol l⁻¹; posterior pituitary extract 1, μg per flask (values in parenthesis are expected ACTH contamination as measured by two radioimmunoassays¹⁹, in mol l⁻¹); Pitressin, pressor units per flask. NS; no stimulation.

that qualitatively similar results were obtained with ACTH, posterior pituitary extract 1, and Pitressin. Corticosterone and 18-hydroxycorticosterone (18-OH-B) are most stimulated, with a smaller increment in aldosterone. The effect on deoxycorticosterone (DOC) is variable, while 18-hydroxy-DOC (18-OH-DOC) is not affected. The response of the steroid profile in intact (non-dispersed) tissue is highly characteristic and contrasts with the effects of potassium ions, or dibutyryl cyclic-AMP, both of which stimulate 18-OH-DOC as well as the other products^{20,21}.

Fig. 1 Profile of steroids obtained during incubation of rat adrenal zone glomerulosa (intact) in control conditions and with the addition of ACTH ($1 \mu\text{g}$ per flask, approximately $5.5 \times 10^{-8} \text{ mol l}^{-1}$), crude posterior pituitary extract 1 ($100 \mu\text{g}$ per flask, approximately $1.5 \times 10^{-7} \text{ mol l}^{-1}$ α -MSH/ACTH as judged by the N-terminal assay) or Pitressin (2 pressor units per flask, approximately $0.6 \times 10^{-7} \text{ mol l}^{-1}$ α -MSH) to the incubation flasks. A characteristic of all these stimulants is that corticosterone, 18-OH-B and aldosterone are stimulated ($P < 0.05$ or better) whereas 18-OH-DOC is not. This contrasts with stimulation by potassium or dibutyryl cyclic AMP, which also stimulate 18-OH-DOC. Values are means \pm s.e.m., $n = 6$ throughout. Male rat adrenals were used for incubation of whole tissue. Pairs of capsules which consist mostly of zona glomerulosa cells but with 5–8% contamination with fasciculata cells were incubated in individual flasks containing 5 ml Krebs–Ringer (without bovine serum albumin (BSA) or collagenase, see legend to Fig. 2). After 1 h preincubation the medium was discarded and the tissue resuspended in fresh Ringer. Incubations, to which stimulants were added, were for 2 h.

Fractionation of Pitressin was achieved using reverse-phase high pressure liquid chromatography (HPLC) in a salt-free system²² (Fig. 2, a similar profile of this preparation has been reported for a salt-based system²³). Assay for glomerulosa cell stimulation shows the activity mostly to be associated with three UV absorbing peaks indicated on the chromatogram (peaks A–C). When these are pooled and tested against unfractionated Pitressin at a range of concentrations, the dose–response curves show that at least 70% of the total glomerulosa stimulating activity in Pitressin is contained in these fractions. From sample to sample of Pitressin, however, their relative amounts vary enormously, even between vials of the same batch. In some samples the UV absorbing peaks are absent altogether, and in these the eluates from the HPLC columns are also devoid of glomerulosa-stimulating activity. Rechromatography of peak A (or B) gives a single peak in the ultraviolet co-incident with biological activity.

Peak A was further characterised in the following ways:

(1) Treatment of the active sample with leucine aminopeptidase and, separately, carboxypeptidase Y did not lead to destruction of the biological activity. However, treatment with elastase destroyed the biological activity and, overall, these data suggested the presence of a peptide blocked both at the N- and C-termini.

Table 2 Amino acid content of tubes 26 to 31 after chromatography of 1 ml of Pitressin on the preparative HPLC column (see legend to Fig. 2)

	Fraction no.					
	26	27	28	29	30	31
Asx	2.7	1.2	3.1	3.4	3.5	3.5
Thr	1.0	0.7	2.0	2.0	2.1	1.7
Ser	2.0	2.1	4.8	6.0	3.4	2.6
Glx	4.3	3.4	6.2	7.1	5.5	4.9
Pro	4.3	1.6	7.6	8.9	5.0	5.2
Gly	3.9	2.2	5.4	6.3	4.8	4.6
Ala	3.2	1.5	3.4	4.1	4.1	4.5
Val	1.7	1.2	2.8	4.3	2.8	2.2
Met	0.6	0.5	1.9	2.4	1.0	0.5
Ile	0.4	0.6	0.6	0.7	0.8	0.8
Leu	1.8	0.8	2.2	2.8	3.2	2.9
Tyr	1.4	0.9	2.3	3.0	1.7	1.0
Phe	2.0	1.4	3.0	3.8	2.3	1.6
His	1.1	1.2	2.3	3.4	1.5	1.2
Lys	1.1	1.0	2.2	2.8	1.6	1.2
Arg	1.1	1.1	2.7	3.5	1.8	1.8

Peaks A and B correspond to tubes 28 and 29 respectively, and a tentative amino acid analysis for peak A is obtained by subtraction of 'blank' tubes (26, 27, 30 or 31) from tube 28. Values are in nmol ml^{-1} .

Fig. 2 UV profile of reverse-phase HPLC fractionation of Pitressin using a $0.39 \times 30 \text{ cm}$ column and the conditions given in ref. 22. A similar UV profile was obtained using a $0.78 \times 30 \text{ cm}$ column in the reported conditions²². The effect on corticosterone synthesis of adding these fractions to incubations of glomerulosa cells is shown in the lower part of the figure. For bioassays Wistar strain rats from the colony maintained at St Bartholomew's Medical College were used. Animals were killed by cervical dislocation, and the adrenals were quickly excised and stored on ice for brief periods before incubation. The glands were decapsulated and the capsules, containing largely zona glomerulosa cells (approximately 7% contamination by inner zone cells) and inner zones (zona fasciculata and zona reticularis) were incubated separately in Krebs bicarbonate Ringer solution (3.6 mM K^+) with 1% BSA (Sigma, fraction V), 200 mg glucose per 100 ml (KRBGA), and 2 mg ml^{-1} collagenase (Worthington). Tissue from 20 animals was incubated in 20 ml medium for 1 h at 37°C under 95% O_2 , 5% CO_2 . The tissue was then disrupted by repeated pipetting, filtered through nylon gauze, and centrifuged at 100g for 10 min. Cells were resuspended in 2 ml medium, and recentrifuged. The supernatant was discarded and the cells resuspended in a volume of incubation medium suitable for dispensing to incubation flasks.

(2) Amino acid analysis of column fractions spanning the biological activity (tubes 26–31) gave the data shown in Table 2. Subtraction of the non-active 'blanks' from the active fractions leads to a tentative conclusion that the active peptide is approximately 15 residues long with 1 Lys and 1 Arg or 30 residues long with 2 Lys and 2 Arg and so on. (3) Mass spectrometric

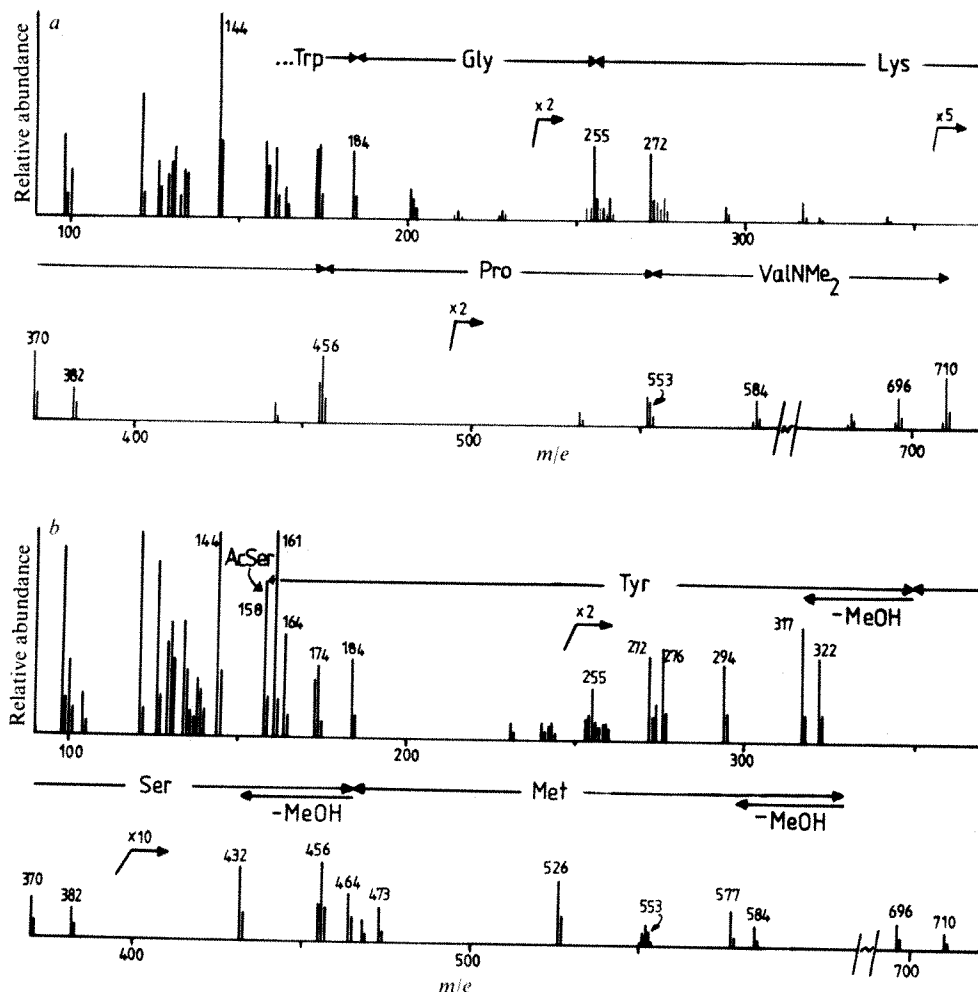

Fig. 3 Electron impact mass spectra of a tryptic digest of peak A at an ion source temperature of 300 °C (a) and at an ion source temperature of 350 °C (b). Spectra were recorded on a Kratos MS 50 mass spectrometer operating with an accelerator voltage of 8 kV and an electron beam energy of 70 eV. Before mass spectrometric examination peak A was dissolved in 100 μ l of 50 mM ammonium bicarbonate and treated with trypsin (1 μ g) for 3 h at 37 °C. After freeze drying the digest was deuterioacetylated and permethylated according to published procedures^{24,25}.

examination after trypsin digestion and derivative formation^{24,25} yielded good spectra; two representative spectra of the active material are shown in Fig. 3. The blocked N-terminus of the peptide is clearly established as acetyl-Ser-Tyr-Ser-Met- via signals at m/e 158, 317, 432, 464, 577 (Fig. 3b) and the blocked C-terminus is identified as Trp-Gly-Lys-Pro-Val-NH₂ via 'N-C cleavage' signals²⁶ at m/e 184, 255, 456, 552, 553, 696, 710 (Fig. 3a). Signals corresponding to an N-terminal Trp sequence, in addition to the N-C cleavage fragments assigned in Fig. 3, were observed in several spectra obtained during the source temperature gradient used for the examination of the tryptic digest of peak A. This suggests that the tryptophan is preceded by Lys or Arg (Arg if there is only one residue of each). Signals at m/e 98, 131, 134, 135 and 138 indicate the presence of glutamic acid, phenylalanine and histidine in the sequence of the molecule, and the lack of additional peptide signals in the spectra suggests that the peptide is likely to be approximately 15 rather than 30 residues in length. Overall the structural data obtained from the mass spectra may be summarised as

(Acetyl-Ser-Tyr-Ser-Met- (Glu, Phe, His) -Arg-Trp-Gly-Lys-Pro-Val-NH₂)
 approximately 15 residues

Comparison of these data with known structures of biologically active peptides suggests the probability that the active component of Pitressin is α -MSH:

Acetyl-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-NH₂,

which has identical N- and C-terminal sequences and whose structure is consistent with the other mass spectrometric and amino acid analysis data.

Accordingly, synthetic α -MSH was chromatographed both separately and together with Pitressin and found to co-elute with

Fig. 4 Effects of α -MSH on rat adrenocortical cells (dispersed, see legend to Fig. 2) as judged by corticosterone production, at various concentrations. All values are means of two observations in a single experiment (that is, a uniform cell crop) except for dotted extrapolations which are based on data derived in a separate experiment.

Fig. 5 Profile of steroids obtained during incubation of rat adrenal zona glomerulosa (intact tissue, see legend to Fig. 1) in control conditions and with the addition of α -MSH ($0.5 \text{ nmol per flask}$, $10^{-7} \text{ mol l}^{-1}$) and Pitressin (4 pressor units, containing approximately $0.6 \text{ nmol } \alpha\text{-MSH}$, $1.2 \times 10^{-7} \text{ mol l}^{-1}$). Qualitatively the results obtained with the two stimulants are similar in that corticosterone, 18-OH-B and aldosterone are all stimulated ($P < 0.05$ or better) whereas 18-OH-DOC is not; effects on DOC are variable. These results parallel those obtained with ACTH and posterior pituitary extract 1 (see Fig. 1). Quantitative differences between the two stimulants are attributable to the inclusion in Pitressin of further peptides (B and C, see Fig. 2) which also stimulate the rat zona glomerulosa cell. Values are means \pm s.e.m., $n = 6$ throughout, except for Pitressin-stimulated DOC, $n = 2$.

peak A. Furthermore, examination of peak A on HVPE gives, on staining with Cd-ninhydrin²⁷, a major spot with identical mobility to α -MSH, in addition to more weakly staining neutral and acidic peptides. Overall, the structural and chromatographic data strongly indicate that the biological activity is derived from α -MSH.

Authentic α -MSH was therefore tested in both types of incubation system (Figs 4 and 5). Clearly the features of the response to α -MSH show many points in common with the response to Pitressin. In the first place, only glomerulosa cells are stimulated, and there is no effect on the fasciculata/reticularis cells (shown to respond normally to ACTH). Second, the pattern of the intact capsule steroid profile and its response to stimulation is similar to Pitressin (and to ACTH, see Fig. 1) in that corticosterone, 18-hydroxycorticosterone and aldosterone were stimulated, whereas DOC and 18-OH-DOC were not affected. Half maximal stimulation with synthetic α -MSH is obtained at about $10^{-8} \text{ mol l}^{-1}$ and with Pitressin at 100 mU per flask (Table I) which from its calculated α -MSH content would

yield about $3 \times 10^{-9} \text{ mol l}^{-1}$ of α -MSH. It seems likely from this data that the stimulatory potential of Pitressin is partly, perhaps 30%, due to α -MSH. In the case of posterior pituitary extract 1 it is also likely that the greater sensitivity of glomerulosa cells (compared with fasciculata/reticularis) to its stimulation may also be due to α -MSH in part, since the N-terminal ACTH assay, with which there is a 100% cross-reaction with α -MSH¹⁹ gave higher values than the C-terminal assay. However, it is also certain that this extract contained intact ACTH and possibly other factors to account for its greater potency when compared with Pitressin on the basis of its N-terminal reactivity (Table 1).

Earlier studies have suggested the stimulation of aldosterone production by α -MSH^{28,29}, and recently it has been shown that cortisol production by fetal human and sheep adrenal cells responds to α -MSH stimulation but this capacity is lost in the adult sheep^{30,31} (although conflicting results have been obtained with rhesus monkey fetal adrenal cells³²). It seems likely therefore that although the major site of steroidogenesis in the adult adrenal, the fasciculata cell, is not responsive to α -MSH, other cell types may retain this capacity.

Whether α -MSH functions as a trophic hormone on the zona glomerulosa in the adult is a matter for further investigation. Reported circulating levels of α -MSH in normal rats are of the order of $10^{-10} \text{ mol l}^{-1}$, below the threshold of stimulation in our experiments (see Fig. 4)³³. However, plasma levels will certainly vary, depending on the physiological condition of the animal, and in this connection it is particularly interesting to note that changes in sodium status in rats exert profound effects on pars intermedia histology and α -MSH content, and thus presumably on α -MSH secretion³⁴⁻³⁶. While it might be expected that a true physiological messenger should (in contrast to the effect of α -MSH) elicit a greater response on aldosterone than on corticosterone, experience with other stimulants such as potassium or angiotensin II added acutely has shown that such 'late pathway' effects are only revealed with the adoption of a harsher methodology (see for example ref. 37). It is also possible that there may be species variation in the response of the zona glomerulosa to MSHs in view of the relative lack of response of the human gland to α -MSH³⁸ and of the sheep gland to β -MSH³⁹.

The identities of the remaining UV peaks (B and C) which are coincident with biological activity are now being determined using the combination of purification and mass spectrometric methods described above.

We thank Drs E. C. Nice and M. J. O'Hare (Ludwig Institute for Cancer Research, Royal Marsden Hospital) for initial fractionation of Pitressin in their system²³. We also thank Dr Myron Miller, Veteran's Administration Hospital, Syracuse, New York) for the gift of posterior pituitary extract 1, Professor Lesley Rees for the radioimmunoassays on this material, and Dr D. M. Burley (Ciba-Geigy) for the gift of ACTH₁₋₂₄ (Synacthen). We are also grateful to MRC for grant support to G.P.V., and the MRC and SRC for grant support to H.R.M.

A newly identified population of presumptive microneurons in the cat retinal ganglion cell layer

A. Hughes & Elzbieta Wieniawa-Narkiewicz

Department of Physiology, The John Curtin School of Medical Research, The Australian National University, PO Box 334, Canberra City, ACT 2601, Australia

A large population of microneurons has recently been discovered in the rabbit retinal ganglion cell layer^{1,2}. These 'coronate' cells may represent a class of displaced amacrine cells^{1,2}. Like conventional amacrine cells³ they are swiftly and selectively destroyed⁴ by low concentrations of kainic acid, a neurotoxin⁵. No similar cell has been described in the cat retina, which is reported to contain 217–260,000 neurones of classical appearance⁶. These outnumber the 128–180,000 optic nerve fibres^{7,8} but it has been suggested that the excess comprise Nissl-staining glial cells⁹. We report here that, using the neurotoxic effects of kainic acid to test and confirm the neuronal nature of the classic neurone excess, a large additional population of at least 730,000 presumptive microneurons was revealed. They resemble rabbit coronate cells, do not project into the optic nerve and have been previously identified as presumed glia^{6,10,11}. Various lines of evidence for the neuronal nature of these cells is presented below, but synapses have not been demonstrated; subsequent reference to microneurons must therefore be regarded as presumptive.

The vitreous humor of cats anaesthetised with Nembutal was injected with either 12 or 120 nM of kainic acid in 10 μ l of saline. After 3 h the retina was removed, mounted and stained⁶.

As shown in Fig. 1, near the area centralis, α , β and larger γ ganglion cells¹² seemed to be normal at the lower dosage but, apart from one microglial cell, none of the remaining non-vascular profiles resembled those of normal retina, and all showed kainic-induced necrocytosis; the nuclei of many were pyknotic⁵. Small γ -mode neurones seemed scarce but the number of necrotic profiles was far in excess of their possible

Fig. 1 Cells in the ganglion cell layer of the cat retina after an intraocular injection of 10 nM kainic acid. They are situated near the 2,500 classic neurones mm^{-2} isodensity line some 1.5 mm temporal of the area centralis. α (a), β (b) and the larger γ (g) Nissl-stained somas are apparent in relatively unchanged form. One γ cell near the centre of the figure has begun to degenerate and shows the characteristic nucleus with clumped chromophilic material. The large, medium and small arrows indicate profiles in progressively more advanced stages of degeneration. The final product is the pyknotic profile designated by the smallest unlabelled arrows. The open arrow indicates a classic glial cell. The degenerating profiles of this region must represent small cells because the densities of large and medium-sized cells are normal. The number of kainic-sensitive cells far exceeds the possible number of degenerate γ cells. Alcohol/formalin-fixed material. Scale bar, 10 μ m.

Fig. 2 a–i, Cells from the untreated cat ganglion cell layer resembling those which are destroyed by kainic acid and have previously been presumed to be glia. Small arrows: RNA-specific basophilia in free cytoplasmic granules; medium arrows: similar material at the juxtannuclear region of the cell's cytoplasmic pole; large arrows: basophilic nuclear invaginations. The nucleolus is obvious in cells of a and e. The subnuclear ring of basophilia is apparent in d, f and i; in i it is below the nucleus. j, k, Cells of the amacrine layer with features resembling those of dispersed, chromatin. These are from an eye injected with 120 nM of kainic acid and enucleated after 3 h, but their appearance is within the normal range. Cells such as those in a–k were destroyed by this treatment although they lie deeper within the retina. Alcohol/formalin fixed. Scale bar 10 μ m.

Fig. 3 A lightly Nissl-stained region of normal retina somewhat more peripheral than that of Fig. 1. The somas of Nissl-stained α (a), β (b) and γ (g) mode neurones are apparent. The small arrows indicate the profiles of cells previously identified as presumed glia^{7,12,13}. A large number of these cells are present, as would be expected in a region of normal retina similar to that shown in Fig. 1. However, no such profiles with relatively clear nuclei and juxtanuclear basophilia can be seen in Fig. 1. A quantitative analysis (see text) shows the majority of the kainic-sensitive profiles to correspond to the small, pale profiles shown here. These presumed glia^{7,13} are thus sensitive to the influence of a neurotoxic compound not known to have gliotoxic effects. Alcohol/formalin-fixed material. Scale bar 10 μ m.

contribution; the surprisingly large population of pyknotic cells was particularly obvious in the periphery, where ganglion cells are less common.

A 0.013-mm² area near that shown in Fig. 1 contained 75 non-vascular profiles. Of these, 2 were classic glia with obvious nuclear chromatin, 2 were α -mode cells, 15 β -mode cells and 8 γ -mode cells; the remainder were unlike any profiles of normal retina. Because this region in untreated retina has a γ -cell population equal to the combined α - and β -mode populations¹³ it is estimated that nine of the novel profiles represent degenerate classic neurones of the γ mode. Thus, 34 profiles (45%) represent classic neurones; 2 (3%) were classic glia and the remaining 39 (52%) represent cells not previously included in the neurone count but which have been destroyed by a neurotoxic compound.

In normal retina this area (Fig. 5A of ref. 6) contains a similar proportion (43%) of classic neurones, but the remaining 57% of profiles are presumed to be glia. The most common of these 'presumed glia' lack the conspicuous nuclear chromatin of classic glia and often possess a prominent nucleolus⁶. In kainic-treated retina only 3% of profiles in the ganglion cell layer were recognisable as glia; the remaining 54% of presumed glia were missing. There was instead a corresponding proportion of 52% residual kainic-damaged profiles which we conclude represents the necrotic presumed glia of the normal cat retina; their absolute densities are similar at 2,800 mm⁻² and 2,960 mm⁻² (ref. 6).

Kainic acid does not seem to be gliotoxic¹⁴; early glial response to kainic acid^{15,16} resembles that to glutamate^{3,17,18} and is reported to involve swelling but not necrosis and pyknosis. The exposed glial cells of the fibre layer and perivascular glia were unchanged in appearance even at the 10 times higher dose of kainic acid (Fig. 2I), as were glia in the ganglion cell and inner plexiform layers. Müller cell bodies and feet seemed normal, without the damage we observe with DL-amino adipic acid, a known gliotoxic compound¹⁹. On this basis, we conclude that the majority of the presumed glia in the normal cat ganglion cell layer are, in fact, neurones.

Figure 3 shows a lightly stained region of normal cat retina; the majority of profiles correspond to the presumed glia of previous reports^{6,9,11}. The pear shape of some cells (Fig. 2), the juxtanuclear basophilia, basophil nuclear invaginations and

Fig. 4 The soma diameter spectrum illustrates the size range of non-vital stained cells in the various classic neurone modes of peripheral cat retina subject to supravital methylene blue staining and non-vital counterstaining. In addition, the stippled regions represent the presumed microneurone spectrum previously identified as presumed glia. The location in the soma size spectrum of some supravital methylene blue-stained microneurones is indicated in black. The partially stained unequivocal neurones *b* to *h* occupy the lower range of the microneurones. A medium-sized γ soma is shown at *a* for comparison. Neurones occupying a region of the diameter spectrum significantly outside the γ mode of classic neurones have not previously been reported. Their presence shows that cells in the class labelled 'microneurones' are not too small to be neurones of the cat retinal ganglion cell layer.

cytoplasmic granules, size range and restricted cytoplasm are similar to those of rabbit coronate cells². Some possess the 'crown' of juxtanuclear basophilia which led to the term 'coronate' in rabbit (Fig. 2*d, f, i*); its basophilia to Galloxyanin-lake is confirmed to be RNA-specific in the cat by its elimination with prior ribonuclease incubation, a result similar to that seen in the rabbit². The complex nuclear form^{20,21}, its basophilic invaginations²¹ and cytoplasmic RNA basophilia²² are characteristically neuronal^{20,21}.

These cells are smaller than any neurones previously described in the cat retinal ganglion cell layer and are different from reported cat displaced amacrine cells²³. Supravital methylene blue-stained retinas were examined for examples of their dendritic trees. Figure 4 shows the diameter range of soma profiles for neurones in such preparations. Dendritic trees are shown only for cells with very small, 5–7 µm, somata well displaced from the γ-mode population. None are completely stained but the variety of form suggests considerable heterogeneity; their vital staining offers additional evidence for their neuronal nature²⁴. Many possess one main dendrite which branches close to the soma. No axons or axon-hillocks were observed and the cells do not fill with horseradish peroxidase from the optic nerve¹³.

In peripheral retina the presumptive microneurones form 75% of the profiles in the retinal ganglion cell layer but their density is lower, 1,550 mm⁻². In a 470-mm² cat retina⁶ this suggests a population of at least 730,000 microneurones. Adding the 217,000 classic neurones⁶ we estimate a population of up to 10⁶ neurones in the cat ganglion cell layer. This is so far in excess of even the largest optic nerve fibre counts that it precludes the possibility of a significant proportion of the microneurones being ganglion cells. That such a large population has remained undiscovered for so long suggests that they are, like the interplexiform cell²⁵, only rarely impregnated by the capricious Golgi stain.

Two classes of neurone which do not project into the optic nerve are recognised in the retinal ganglion cell layer—cells of Marengi^{26,27} and displaced amacrine cells²⁸. Cells of Marengi, unlike the microneurones of cat and rabbit retina, possess an axon. However, cells similar to microneurones do occur in the amacrine layer (Fig. 2*j, k*) of both species. Rabbit coronate cells², cat microneurones and non-displaced amacrine cells³ are all sensitive to kainic acid. It is concluded that the microneurones represent a class of 'displaced' amacrine cell. There are additional reasons for assuming this in the rabbit².

Displaced amacrine cells are regarded as common in non-mammalian species²⁸ but have only occasionally been identified in mammals^{23,28–30}. Their large number in the bird retina^{31,32} has been well demonstrated³³. Now cat, rabbit^{1,2} and rat³⁴ are also known to possess a large population of neurones in the ganglion cell layer which are not ganglion cells. No distinctive role has been postulated for either displaced amacrine cells or the microneurone population. The relative uniformity of microneurone density across the retina suggests that these cells function in relation to a fixed-size module of inner nuclear layer neurones.

A role for collagen in the pathogenesis of muscular dystrophy?

V. C. Duance*, H. R. Stephens†§, M. Dunn†, A. J. Bailey‡ & V. Dubowitz‡

*Department of Animal Husbandry, University of Bristol, Langford House, Langford, Bristol BS18 7DU, UK †Jerry Lewis Muscle Research Centre, Department of Paediatrics and Neonatal Medicine, Hammersmith Hospital, Du Cane Road, London W12 0HS, UK ‡Agricultural Research Council, Meat Research Institute, Langford, Bristol BS18 7DY, UK

The extensive proliferation of connective tissue in muscular dystrophy caused Duchenne¹ to term it 'paralysie myosclerosique'. Surprisingly, there has been little interest in the pathogenesis of this marked fibrosis or of the fat replacement in dystrophic muscle. The fibrosis has generally been considered secondary, with various hypotheses² to explain the fundamental cause of muscular dystrophy. Several authors have commented on the increased endomysial stroma early in the disease before any apparent muscle degeneration^{3,4} and have suggested that there might be an aberration in the production of connective tissue in muscular dystrophy and that the thickening pericellular reticulum would adversely affect muscle nutrition^{5,6}. Ionasescu and his collaborators found an over-production of connective tissue with a concomitant decrease in muscle protein synthesis both by polyribosomes from skeletal muscle and by tissue culture of muscle tissue and skin fibroblasts from patients suffering from Duchenne muscular dystrophy^{7–9}. Thomson *et al.*¹⁰ have observed in tissue culture that dissociated muscle from patients with Duchenne and Becker muscular dystrophy will form unusual clusters of 'sticky' cells, which they suggested may reflect an abnormal collagen production. These findings have cast doubts on the interpretation that the extensive connective tissue proliferation characteristic of Duchenne muscular dystrophy, and also seen in limb-girdle, Becker and congenital dystrophies, is simply due to a compensatory replacement of the wasting muscle¹¹ but infers a more primary role for the connective tissue collagen. Only recently has the role of connective tissue in developing muscle come to be appreciated^{12–14}. Moreover, immunofluorescent techniques^{14–16}, now allow investigation of the various types of collagen present in skeletal muscle. We report here on the localisation and change in proportion of collagen types I, III, IV and V in muscle from patients with various forms of neuromuscular disease, and propose a more positive role for collagen.

Needle biopsies were obtained from 15 patients (2–12 yr old) suffering from Duchenne and limb-girdle muscular dystrophy as assessed by clinical, and histological criteria¹¹. Collagen types I,

§ Present address: Department of Anatomy, Université de Montréal, Case Postale 6128, Succursale "A", Montréal PQ, Canada H3C 3J7.

Fig. 1 Immunofluorescence staining of transverse sections ($\times 60$) of normal (*a, b*) and dystrophic human muscle (*c, d*) with antibodies to type III (*a, c*) and type IV (*b, d*) collagen. Cryostat sections were stained by the indirect procedure using a fluorescein-labelled anti-rabbit or anti-goat IgG for the second stain. The excessive deposition of type III collagen in muscular dystrophy is readily observed when compared with normal muscle (*a, c*). This increase in type III collagen is distributed in the perimysium (P) and the endomysium (E). The apparent endomysial basement membrane thickening is seen when comparing normal muscle (*b*) with diseased muscle (*d*) stained with anti-type IV antibodies. Note also the more prominent blood vessels (BV) in the diseased muscle. Less dramatic changes are observed with sections stained with antibodies to types I and V (not shown).

III, and IV were localised by fluorescent antibody staining techniques¹⁵ on cryostat sections. The antibodies were raised in rabbits or goats using purified human collagens¹⁷. Antisera were rendered type specific by passage through a series of immunoabsorbent columns with types I–V collagens covalently coupled to Sepharose-4B. The antibodies were assayed by passive haemagglutination for activity and specificity. No cross-reactivity was observed at the lowest dilution used (1/4) with antibody titres ranging over 1/64–1/1,024. The anti-collagen antibodies used for the immunofluorescence staining were diluted to give titres of 1/50–1/100; the fluorescein-conjugated anti-rabbit IgG (Wellcome) and fluorescein-conjugated anti-goat IgG (Miles) were used as recommended by the suppliers.

The distribution of these various collagen types in normal human muscle paralleled that previously found in bovine and chick skeletal muscle^{14–16}. Antibodies to type I collagen stained the epimysium and tendon bundles with slight staining of the perimysium; anti-type III, although staining the epimysium, exhibited a much greater affinity for the perimysium and endomysium between the muscle fibres (Fig. 1*a*); anti-type IV stained the contours of individual muscle fibres intensely, as would be expected for this basement membrane collagen (Fig. 1*b*); anti-type V was also present in the endomysial basement membrane surrounding each muscle fibre, although there was also slight fluorescence in the perimysium.

The most striking feature of Duchenne muscle was the vast anti-type III staining in the peri- and endomysial tissue around the muscle fibres, some of which were small and either atrophying or regenerating and others which were hypertrophied (Fig. 1*c*). The enhanced type III staining was present even in pre-

clinical cases and was a consistent feature of all patients examined. In later stages of the disease the relative increase in type III collagen was proportionately less due to the massive adipose tissue replacement. The vast proliferation of type III collagen in muscle is typical of the response of tissue to injury, as observed in wound healing¹⁸.

The prominent variation in fibre size characteristic of muscle from patients with Duchenne and limb-girdle muscular dystrophies could readily be seen when the endomysial basement membrane anti-type V collagen was stained with anti-type IV (Fig. 1*d*) and anti-type V collagen. Further, the staining of the basement membrane with anti-type IV and V collagen was occasionally more intense around smaller muscle fibres. Whether this reflects a thicker basement membrane or a more extensive infolding of the basement membrane coincident with myofibrillar loss¹⁹ remains to be resolved, perhaps with electron microscopy. Many of the circular profiles which stain prominently with anti-type IV collagen are small capillaries (see Fig. 1*d*). They are much more marked in biopsied muscle in cases of Duchenne muscular dystrophy, which agrees with Jerusalem's observation of reduplicated basement membrane forming two or more continuous or discontinuous layers around the vessel and of an increased mean capillary area²⁰ in Duchenne dystrophy. On the other hand, some of the small fluorescent profiles may be surviving remnants of muscle basement membrane^{21,22}.

The presence of thickened basement membrane and the observation of splits within a few of the muscle fibre bundles from Duchenne and limb-girdle patients are characteristic of muscle disease and muscle injury^{21,23–25}. The appearance of splits in hypertrophied and whorled fibres may denote an early stage in the breakdown of the muscle fibre. Our present finding of type III and IV collagen in these splits (Fig. 2) suggests that collagen may play a part in this process. The recognition of the importance of connective tissue components in muscle disease should provide further impetus in the study of the aetiology of muscular dystrophies.

This investigation was supported in part by the Arthritis and Rheumatism Council (VCD), Muscular Dystrophy Association of Canada, the Muscular Dystrophy Group of Great Britain (HRS) and the Medical Research Council (MD). We thank Mrs C. Hutson for technical assistance.

Fig. 2 Transverse section of dystrophic muscle ($\times 146$) stained as in Fig. 1 with anti-type IV collagen. Note the presence of staining in the split within the muscle fibre.

Haloperidol-induced catalepsy is mediated by postsynaptic dopamine receptors

Paul R. Sanberg

Department of Behavioural Biology, Research School of Biological Sciences, Australian National University, Canberra City, ACT 2600, Australia

Antipsychotic or neuroleptic drugs, which block central dopamine receptors, produce a behavioural state in animals in which they fail to correct externally imposed postures. This is referred to as catalepsy. Previous lesion studies have shown that the dopamine receptors in the striatum are involved in this neuroleptic-induced catalepsy^{1–5}. Dopamine receptors, identified by the specific, high-affinity binding of the potent neuroleptic haloperidol, have been shown to be equally distributed postsynaptically on striatal neurones and presynaptically on cortico-striatal terminals^{6–9}. Because the electrolytic lesioning studies^{1–5} have unavoidably damaged both pre- and post-synaptic striatal dopamine receptors, it is not known whether these two receptors are separately involved in neuroleptic-induced catalepsy. Using kainic acid and cortical ablation to destroy postsynaptic and presynaptic dopamine receptors, respectively^{6–9}, the present study demonstrates that the cataleptic effects of haloperidol are apparently mediated by dopamine receptors localised postsynaptically on striatal neurones.

Ten male Wistar hooded rats weighing about 350 g received 6 nmol of kainic acid injected stereotactically into each striatum^{10,11}. Ten control animals received vehicle injections only. In another eight rats the parietal and frontal cortex was removed. Nine control animals received sham operations. All the rats received a prophylactic subcutaneous injection of aquacaine (0.2 ml) and an intraperitoneal (i.p.) injection of diazepam (5 mg per kg) immediately following surgery (diazepam reduces the possibility of extrastriatal damage in rats injected with kainic acid^{12,13}). All animals were allowed to recover for 4 weeks before testing for catalepsy. After testing, the animals were perfused intracardially with 10% formol saline and their brains examined histologically. Consistent with previous reports^{10,11,14,15}, the kainate-lesioned rats showed a considerable loss of neuronal cell bodies in the dorsal two-thirds of the striatum, whereas very little extrastriatal damage was apparent.

In all rats with cortical ablation there was no destruction below the level of the corpus callosum.

The cataleptic effect of the central dopamine receptor blocker haloperidol (1 mg per kg) on kainate-lesioned and cortex-ablated rats is shown in Fig. 1. Catalepsy was measured by gently placing the animal's forepaws on a horizontal bar located 8.0 cm above the floor and timing the period before the animal placed at least one paw on the floor. If an animal remained on the bar for more than 5 min, it was removed and a score of 300 s was given. After saline injections, rats in all groups typically removed their paws from the bar within 20 s. The decorticate rats, however, showed slightly higher descent latencies under saline compared with their control group ($P < 0.05$). This may be due to an increased emotionality, as they defaecated substantially more than controls during testing. Injection of haloperidol induced considerable catalepsy in the control animals (Fig. 1). Haloperidol-induced catalepsy was almost totally blocked in the kainate-lesioned rats ($P < 0.01$). By contrast, haloperidol tended to increase catalepsy in decorticate rats, although this increase did not reach significance ($P < 0.07$).

It has previously been demonstrated^{6–9} that kainic acid-induced striatal lesions destroy about 40% of ³H-haloperidol binding sites in the striatum, demonstrating postsynaptic localisation on intrinsic striatal neurones. Decortication, which removes the cortico-striatal tract, resulted in a similar reduction of ³H-haloperidol binding, showing presynaptic localisation of dopamine receptors on cortico-striatal afferents. Although previous studies^{1–5} have shown that haloperidol-induced

Fig. 1 Catalepsy induced in control (CON), kainate-lesioned striatal (KAL) and cortically ablated (CTX) rats. KAL rats ($n = 10$) were injected with 6 nmol kainate dissolved in 1.0 μ l of phosphate-buffered isotonic saline solution, pH 7.2, as described elsewhere^{10,11}. CON rats ($n = 10$) received infusions of the vehicle. CTX rats ($n = 8$) were anaesthetised with sodium pentobarbital (50 mg per kg i.p.) and positioned on a Kopf stereotaxic instrument. The skin was reflected, the calvaria overlying the parietal and frontal cortex was removed, and the underlying cortex was removed to the level of the corpus callosum by aspiration; bleeding was controlled by gelfoam. CON rats ($n = 9$) received sham operations. The data represent the pooled mean results of four catalepsy tests on each rat carried out at 1-h intervals following drug administration. Haloperidol was dissolved in 0.9% saline and injected i.p. at 1 mg per kg. All animals were injected with either haloperidol or saline in a randomly paired fashion. One week later, the other drug solution was administered. The experiment was run blind insofar as the drug solutions were coded. Control and lesioned groups differed at the following levels of significance using a two-tailed Mann-Whitney U test¹⁶: *, 7%; **, 5%; ***, 1%.

catalepsy seems to be mediated by dopamine receptors in the striatum, the electrolytic lesioning techniques used have been unable to examine specifically the roles of these two dopamine receptors in mediating the behavioural response. My results show that the cataleptic response to haloperidol injection is almost completely abolished in kainic acid-lesioned rats. The marginal increase in catalepsy induced by haloperidol in these animals may be due to the fact that destruction of the striatal interneurons is incomplete. If anything, haloperidol is more effective in inducing catalepsy in decorticate animals. This suggests that haloperidol-induced catalepsy requires the binding of haloperidol to postsynaptic dopamine receptors in the striatum⁶⁻⁹. The present findings may have relevance for understanding differences in antipsychotic potency of neuroleptic drugs in diseases with cortical and/or striatal atrophy.

I thank Professors R. F. Mark and I. Creese and Drs I. G. Morgan, D. Ehrlich, M. Pisa and I. J. Faulks for helpful comments, Roche (Australia) for the gift of diazepam, and Janssen (Belgium) for the gift of haloperidol. The author is an ANU Research Scholar.

Cell-free synthesis of enterotoxin of *E. coli* from a cloned gene

Richard Lathe & Peter Hirth

Molekulare Genetik der Universität Heidelberg, Im Neuenheimer Feld, 6900 Heidelberg, FRG

Michel DeWilde, Nigel Harford & Jean-Pierre Lecocq

Smith Kline-RIT s.a., Rue de l'Institut, 1330 Rixensart, Belgium

In a variety of mammalian species including humans the newborn young are particularly susceptible to diarrhoeal disease brought about by toxin-producing strains of the common gut bacterium, *Escherichia coli*¹. Two types of enterotoxin have been described². The first, heat-labile toxin (LT), sharing partial antigenic identity with cholera toxin^{2,3} is comprised of two subunits having molecular weights of 25,500 and 11,500⁴ and, like cholera toxin, stimulates adenyl cyclase activity in the gut⁵. The second type, heat-stable toxin (ST), is a low-molecular weight protein which is excreted into the medium during the growth of ST-elaborating strains. Unlike LT, ST is poorly antigenic and for this reason the identification of ST-producing strains has relied on an assay involving the intragastric injection of infant mice, a test specific for ST⁶. Although many strains produce both ST and LT, strains producing ST alone are especially common in *E. coli* diarrhoeal disease of calves^{7,8}, pigs² and have also been implicated in outbreaks of diarrhoea in humans^{9,10}. Recent evidence suggests that ST activates guanylate cyclase in the gut^{11,12} and its molecular weight has been estimated to be 4,400-5,100 (ref. 13). We have now applied gene cloning techniques to the isolation of ST genes from two porcine *E. coli* isolates and report here the identification of the protein

product of molecular weight 7,000, synthesised in an *in vitro* system directed by the cloned DNA template. This *in vitro* gene product elicits a typical ST enterotoxin response in the infant mouse assay and is most probably synthesised as a 10,000 molecular weight precursor, as might be expected for an exported protein. The gene cloning data also provide evidence that the ST genes and their surrounding transposon structures are probably identical in both porcine and bovine strains of enteropathogenic *E. coli*.

The ability to produce either LT or ST, or both enterotoxins, has been shown in many instances to be a plasmid-mediated trait¹⁴⁻¹⁶. So, Heffron and McCarthy¹⁷ have used molecular cloning techniques to show that the plasmid-borne ST-coding region from a bovine *E. coli* isolate (B41) is located within a transposable DNA element (transposon Tn1681), the structural gene being flanked by inverted repeats of the IS1 insertion sequence.

We have found that commencing with two ST-elaborating porcine isolates (P288 and P310) of *E. coli*, the ST-coding region can be isolated on a *Pst*I endonuclease fragment of molecular weight (MW) 1.05×10^6 , cut symmetrically from within the IS1 sequences of the transposon¹⁸. Since the restriction endonuclease maps of the two porcine *Pst*I fragments are identical in number of sites and size of fragments with the data for the bovine ST gene (ref. 17; M. So, personal communication) we surmise that the ST genes and their transposon structures are identical in all three strains.

The ST-DNA contained within the *Pst*I fragment obtained from the porcine P310 isolate was further subcloned into plasmid pACYC184 (ref. 19). The central *Hae*III fragment was 'flush-end' ligated into plasmid pACYC184 which had been digested with *Eco*RI and the cohesive ends filled in by treatment with avian myoblastosis reverse transcriptase. This results in the regeneration of *Eco*RI sites at the termini of the original *Hae*III fragment. The recombinant plasmid pRIT 10211 so-formed was further manipulated to obtain pRIT 10220 by excising the ST-coding region with *Eco*RI and *Taq*I endonucleases and ligating the resulting fragment into the plasmid vector pBR322 (ref. 20) which had been digested with *Eco*RI and *Cl*aI. In this construction all IS1-sequence DNA has been removed from one side of the ST-DNA insert. The relevant structures of pRIT 10211 and pRIT 10220 are shown in Fig. 1.

These recombinant plasmids were then examined for their ability to stimulate protein synthesis in an *in vitro* transcription-translation system prepared from ST-free *E. coli*²¹. After incubation of plasmid DNA with a reconstituted extract of *E. coli* in the presence of ³H-leucine, newly-synthesised proteins coded by the plasmid were separated by polyacrylamide gel

Fig. 1 Restriction endonuclease maps of recombinant ST plasmids. a, Map of the *Pst*I ST-DNA fragment isolated from strain P310 (compare ref. 17). The shaded bars indicate the extent of the IS1 sequence flanking the ST structural gene. b, pRIT 10211: the central *Hae*III ST-DNA fragment has been inserted at the *Eco*RI site of plasmid vector pACYC184. c, pRIT 10220: the *Eco*RI-*Taq*I ST-DNA fragment from pRIT 10211 subcloned into plasmid vector pBR322. The position of the ST gene is inferred from the fact that insertion of a foreign DNA sequence at the *Hinc*II site destroys ST gene activity and that both central *Alu*I fragments are necessary for ST biosynthesis¹⁷.

electrophoresis in the presence of SDS and subsequently revealed by autoradiography. Figure 2a shows that both pRIT 10211 and pRIT 10220 stimulate the synthesis of a protein of molecular weight 10,000 which is absent from the controls.

To identify this protein as the product of the ST gene, an extract of labelled proteins prepared by *in vitro* transcription of pRIT 10220 was analysed for the presence of material reacting with antibody raised against purified ST. Proteins binding non-specifically to antibodies were first removed from the extract by sequential adsorption to pre-immune serum and Sepharose-coupled protein A from *Staphylococcus aureus*. The extract was subsequently incubated with immune serum and the specific antibody-antigen complexes so-formed examined by electrophoresis in the presence of SDS. Figure 2b not only shows that

Fig. 2 *In vitro* synthesis and immunoprecipitation of plasmid-coded proteins. *a*, *In vitro* transcription-translation reactions were performed in the conditions described in ref. 21 in a final volume of 30 μ l containing 2 μ g of DNA and 50 μ Ci 3 H-leucine. After 30 min at 37 $^{\circ}$ C the proteins were acid-precipitated, applied to an exponential 8–25% polyacrylamide gel using a standard buffer system²⁴ and subsequently visualised by fluorography²⁵. DNA samples were (1) no DNA, (2) pRIT 10220, (3) vector pBR322, (4) pRIT 10211, (5) vector pACYC184. Figures give the MW $\times 10^3$. The 29,000 MW protein present in slots 2 and 3 has not been rigorously identified; the 22,000 MW protein present in slot 5 but absent from 4 is probably the product of the gene encoding chloramphenicol resistance since the insertion into the *Eco*RI site of pACYC184 disrupts this gene¹⁹. *b*, pRIT 10220 DNA was transcribed and translated as described in (*a*). The sample was diluted to 200 μ l in a final concentration of 0.5 M KCl, 100 mM Tris-HCl pH 8.8, 2% Triton X-100, 100 μ g ml⁻¹ each of soybean trypsin inhibitor and phenylmethyl sulphonyl fluoride, and treated sequentially with 2 μ l of pre-immune serum (1 h, 25 $^{\circ}$ C) and 5 mg protein A-Sepharose (Cl-4B, Pharmacia) (1 h, 25 $^{\circ}$ C). The supernatant after centrifugation was treated with 5 μ l of immune serum (18 h, 4 $^{\circ}$ C) and 8 mg protein A-Sepharose (1 h, 25 $^{\circ}$ C). The Sepharose was collected by centrifugation, washed extensively, and bound proteins denatured and examined by SDS gel electrophoresis and fluorography as before. Slot 1 is the anti-ST immunoprecipitate and slot 2 contains marker proteins. The anti-ST immune serum was raised against modified purified toxin and has been shown to seroneutralise both purified preparations of ST and culture supernatants from ST producing bacteria in the baby mouse test. Preimmune sera from the same rabbits were ineffective in this test.

the 10,000 MW protein reacts with the anti-ST serum, but further reveals a second smaller protein (MW ~7,000) which also reacts with the serum.

The appearance of two proteins both of which react with the anti-ST serum suggests that the larger protein might be the primary translation product of the ST gene, and that the ST protein, in common with many other exported proteins²², would also be subject to specific proteolytic processing associated with trans-membrane transport. In support of this hypothesis are the findings that not only is the *in vitro* transcription/translation

Table 1 Biological activity of ST enterotoxin synthesised *in vivo* and *in vitro*

Source of toxin	No. of mice	Body weight (g)	Gut weight (g)	Ratio
<i>E. coli</i> C600/pRIT 10220 culture supernatant	4	7.415	0.826	0.1214
	4	6.985	0.881	
	4	6.949	0.885	
<i>E. coli</i> C600/pBR322 culture supernatant	4	6.901	0.367	0.0542
	4	6.195	0.351	
	4	6.651	0.352	
<i>In vitro</i> synthesis directed by pRIT 10220 DNA	4	7.023	0.869	0.1237
<i>In vitro</i> synthesis directed by pBR322 DNA	4	6.539	0.418	0.0639
<i>In vitro</i> synthesis mixture, no exogenous DNA	4	6.864	0.427	0.0622

One-day-old mice were injected intragastrically with 0.025 ml of culture supernatant of *E. coli* grown to saturation in Trypticase Soy Broth (Difco) medium or with 0.05 ml of *in vitro* transcription/translation mixture directed by 27 μ g of plasmid pRIT 10220 DNA. The mice were killed after 2 h at 28 $^{\circ}$ C and the carcass and intestines separated and weighed. A gut/body ratio of 0.075 is considered weakly positive, a ratio of 0.100 or above strongly positive.

system partially active in the processing of another exported polypeptide, the penicillinase from *Bacillus licheniformis*²³ but also the published MW of the purified toxin (5,000)¹³ is, within experimental error, in accord with that estimated for the smaller protein (MW 7,000) described here.

By comparison with the relative intensities of the marker proteins in Fig. 2, we were able to estimate that 2 μ g of plasmid pRIT 10220 was capable of directing the synthesis of some 0.5–5 ng of toxin in our standard assay conditions. This result encouraged the scaling up of the reaction and direct biological assay of the products of synthesis by intragastric injection of infant mice. The results shown in Table 1 demonstrate that the incubation of cloned ST-DNA in a coupled RNA- and protein-synthesising system results in the appearance of biologically active heat-stable enterotoxin.

We thank Drs L. Dobrescu and F. Van Wijnendaele for rabbit anti-ST antiserum and Miss M. Peeters for performing the infant mice assays. These investigations were supported in part by a grant to Smith Kline-RIT from IRSIA (Belgium).

Vegetative *Dictyostelium* cells containing 17 actin genes express a single major actin

Joel Vandekerckhove* & Klaus Weber

Max Planck Institute for Biophysical Chemistry,
D-3400 Göttingen, FRG

Although actin is highly conserved between different eukaryotic species¹⁻³, six tissue-specific actins have been characterised in higher vertebrates by complete amino acid sequence analysis (two cytoplasmic actins, two smooth muscle actins and two sarcomeric actins)⁴⁻⁸. Their tissue specificity suggests they may differ in some important although unknown physiological property. Actin expression in lower eukaryotes seems to be a simpler process than in higher eukaryotes since biochemical experiments have indicated only one major type in purified preparations from various species^{1-3,9-12}. However, Firtel *et al.* have isolated several recombinant plasmids containing sequences of *Dictyostelium discoideum* DNA complementary to actin messenger RNA¹³⁻¹⁵ and have suggested that this unicellular slime mould may have 17 actin genes^{15,16} potentially giving rise to several different actins. We have, therefore, determined the complete amino acid sequence of actin from vegetative *Dictyostelium* cells. This sequence is unique and agrees with the DNA sequences of four actin genes for that region of the DNA, which is currently known. The protein sequence does not agree with the three other 'genes' and we discuss the possible expression of minor actin species.

Figure 1 shows the primary structure of actin purified¹¹ from vegetative cells determined by procedures used to study amino acid sequence homologies in actins^{5,6}. Comparison with the sequence of actin from *Physarum polycephalum*³ shows that the two proteins differ by only four exchanges. Three of these involve conservative replacements of uncharged amino acids in positions 189, 228 and 313, and the fourth at position 1 involves a charged residue; here *Dictyostelium* actin has aspartate whereas *Physarum* actin has glutamate. Comparison of the sequences of the two lower eukaryotic actins to those of the mammalian cytoplasmic actins⁶ shows that substitutions are not

Fig. 1 The amino acid sequence of actin purified from vegetative cells of *Dictyostelium discoideum*. The order of the proteolytic fragments in the polypeptide chain is based on the homology with the known sequence of rabbit skeletal muscle actin¹⁷ taking into account the minor revisions proposed subsequently^{3,6,18}. An extra residue following residue 234 has been found in all actins so far studied and has been most likely overlooked in the original rabbit skeletal muscle actin sequence. To avoid renumbering of the previously documented amino acid exchanges past this residue we follow the proposal¹⁸ to indicate this residue as 234a. X is the acetyl blocking group¹² typical for all actins and His^{Me} is N¹-methyl-histidine. Residues shown in the top line of the boxes indicate the corresponding amino acid residues in the actin from *Physarum polycephalum*³.

distributed randomly, but are concentrated in residues 1 to 6 and occur occasionally past residue 159. Residues 7 to 159 seem conserved, as only one change has been detected. The same region of mammalian skeletal muscle actin differs from cytoplasmic actins by 7 replacements⁶, suggesting perhaps functional importance of this part for non-muscle actins.

Table 1 summarises the codons at the 5'-end of the *Dictyostelium* actin genes which could give rise to amino acid

Table 1 Summary of DNA sequence data for seven actin genes (from ref. 16) compared to the major *D. discoideum* actin (see Fig. 1)

Positions in amino acid sequence	0	1	2	3	12	15	16	17	30	34	38	40
Genes	Codons of DNA sequence of actin genes											
pcDs actin B ₁	AUG	GAC	GGU	GAA	AAU	GGU	AUG	UGU	GUU	AUU	CCA	CAC
pDd actin 2-Sub 1	AUG	GAU	GGU	GAA	AAC	GGU	AUG	UGU	GUU	AUU	CCA	CAU
pDd actin 7	AUG	GAC	GGU	GAA	AAU	GGU	AUG	UGU	GUU	AUU	CCA	CAU
pDd actin 5	AUG	GAC	GGU	GAA	AAC	GGU	AUG	UGU	GUU	AUU	CCA	CAC
Corresponding amino acid in actin of <i>Dictyostelium</i>		Asp	Gly	Glu	Asn	Gly	Met	Cys	Val	Ile	Pro	His
pDd actin 3	AUG	GAA	AGU	GAA	AAU	GGU	AUG	UGU	CUU	AUU	CCU	UAU
M6	AUG	GAC	GGU	GAA	AAU	GGA	AUG	UGU	CUU	AUU	CCU	UAU
									Leu			Tyr
pDd actin 2-Sub 2	AUG	GAA	UGU	GGA	AAA	AGU	AUA	AGU	GUU	AAU	CAA	UAU
		Glu	Cys	Gly	Lys	Ser	Ile	Ser		Asn	Gln	Tyr

Only those codons are given where the presumptive actin gene products give rise to different amino acid residues. Nomenclature for actin genes is taken from ref. 16. The amino acid differences predicted by genes pDd actin 3, M6 and pDd actin 2-Sub 2 are indicated. The methionine residue at position 0 is due to initiation of protein synthesis and removed post-translationally before acetylation of the aspartic acid at position 1 (reviewed in ref. 19).

differences in the N-terminal part of the actin polypeptides (data taken from Firtel *et al.*¹⁶). On comparison with the amino acid sequence (Fig. 1) three different gene types can be distinguished. The first includes pDd actin 2-Sub 1, 5, 7, and pcDd actin B₁, the only clone synthesised from poly(A) containing mRNA. Although these four genes show subtle nucleotide differences they code for the same protein sequence, which agrees fully with the actin sequence given above. In the case of gene pDd actin 7 a complete correlation for the first 67 amino acids is possible. Provided further analysis does not reveal differences between DNA and protein sequence, the genes could all be true actin genes coding, either simultaneously or at different times of the cell and/or differentiation cycle, for the major cellular actin. The second gene type gives rise to actins differing from the major actin in only a few positions; out of the 50 residues currently covered by DNA sequence; pDd 3 actin differs in four and M6 actin in two amino acids (discussed below). Gene pDd actin 2-Sub 2 provides the third gene type. It comprises a putative actin with a high number of exchanges: that is, 10 for the first 40 residues predicted by the current DNA data (Fig. 1, Table 1). Although this divergence (25%) is only slightly higher than that observed in the same region between mammalian skeletal muscle actin and mammalian β -cytoplasmic actin (20%)^{4,6}, a change in the alignment of clustered constant residues typical of the N-terminal regions of all eukaryotic actins^{3,5} so far studied is predicted (note position of cysteine and lysine residues). Therefore if pDd 2-Sub 2 actin is expressed at all, it may be involved in special functions.

Are genes pDd 3 and M6 silent or are they active at a low level or only at specific times during cellular differentiation? Some of the amino acid differences predicted by the DNA sequence would give rise to charge differences in the resulting actins. Several arguments indicate that the two predicted actins could only be expressed at less than 5% of the level of the major actin. First, the tryptic peptide containing at position 30 the presumptive valine to leucine change of M6 and pDd 3 actin (Table 1), would co-migrate in the fingerprint system with the corresponding peptide of the major actin. As the latter peptide does not contain leucine, it is possible to quantify the amount of M6 and pDd 3 actins by the amount of leucine detectable. Amino acid analysis indicates that M6 and pDd 3 actin, if present at all, can maximally account for 5% of the major actin type. Second, the histidine to tyrosine exchange at position 40 (Table 1) would alter the isoelectric point of pDd 3 and M6 actins. This change would also produce an additional more acidic peptide covering residues 40–50. Since such changes were not found, it can be concluded that if genes pDd 3 and M6 are expressed, the corresponding actins can account together for maximally 10% of the final purified actin. Also, because the purification procedure isolates only ~30% of the cellular actin¹¹, the possibility that certain actin forms were lost preferentially cannot be excluded. To avoid this problem we used a method to characterise actins by the identification of the N-terminal tryptic peptide (residues 1–18). This very acidic peptide can be specifically isolated from a tryptic digest of ¹⁴C-carboxymethylated total cellular protein and then characterised in a two-dimensional paper electrophoresis system⁴. Figure 2 shows the *Dictyostelium* actin N-terminal tryptic peptide in this system together with the corresponding peptides from five different bovine actins and *Physarum* actin. The results show that vegetative *Dictyostelium* cells express only one actin (Fig. 2C). Its N-terminal peptide migrates slightly more acidically than the corresponding peptide of *Physarum*, in agreement with the aspartate to glutamate exchange at position 1 (see above). There is no evidence for actin types with N-terminal peptides different from the one predicted by the first type of genes (see Table 1). The N-terminal peptide expected from pDd 3 actin is clearly absent. This peptide should migrate like the *Physarum* peptide as it differs only at position 2 by a serine to glycine change. From the ratios of label present in the spot of the *Dictyostelium* actin peptide and the area in the map corresponding to the position of the presumptive pDd 3 actin derived peptide, the latter actin

Fig. 2 Two-dimensional separation pattern of the ¹⁴C-carboxymethylated actin N-terminal tryptic peptide from a complete lysate of vegetative cells of *Dictyostelium* (spot 7). This peptide is compared with the corresponding peptides isolated from the following bovine actins: α -like smooth muscle actin of aorta (spot 1), γ -like smooth muscle actin of the rumen (spot 2), β -non-muscle actin (spot 3), γ -non-muscle actin (spot 4), α -skeletal muscle actin (spot 5) and the corresponding peptide from *Physarum polycephalum* (spot 6). A, bovine actins (spots 1–5); B, bovine actins (spots 1–5) + vegetative *Dictyostelium* actin (spot 7); C, *Dictyostelium* actin (spot 7); D, *Dictyostelium* actin (spot 7) + *Physarum* actin (spot 6); E, *Physarum* actin (spot 6). Horizontal separation is by electrophoresis at pH 3.3 and vertical separation is by electrophoresis at pH 6.5. For methods see refs 4 and 5.

could maximally be present at less than 6% of the total actin of vegetative cells.

Thus our studies have not detected minor actin species in addition to the unique actin type for which we provide the complete amino acid sequence. This sequence is compatible with the DNA sequences of four actin genes but does not accommodate the other three currently described. It remains possible that the other genes code for actins present either at very low level in vegetative cells or expressed only at specific times during cellular differentiation, particularly since different isoelectric forms of actin have been reported in one¹⁵, but not a second¹², *in vitro* translation study. The methods described here should provide answers to these questions when cells at different developmental stages and actins translated *in vitro* are used.

We thank Dr J. Spudich for a gift of purified *Dictyostelium* actin, M. Puype for technical assistance and Drs M. Osborn and A. Bretscher for discussions. J.V. is bevoegdverklaard navorser at the Belgian National Fund of Scientific Research and thanks the NFWO for a grant.

Note added in proof: We have now shown that preaggregation cells of *Dictyostelium* also show the same N-terminal peptide as vegetative cells.

Long spacers among ribosomal genes of *Drosophila melanogaster*

Zena K. Indik & Kenneth D. Tartof

The Institute for Cancer Research, 7701 Burholme Avenue, Philadelphia, Pennsylvania 19111

The fruit fly, *Drosophila melanogaster*, has 200 tandemly arranged copies of the ribosomal RNA genes (rDNA) per haploid genome^{1,2}. One such cluster of rRNA genes occurs on the X and one on the Y chromosome. The basic repeating unit of the rRNA gene consists of a segment coding for 18S rRNA and 28S rRNA followed by a non-transcribed spacer³ (Fig. 1). In the X chromosome, there are two major size classes (12 and 17 kilobases) and numerous minor size classes of rDNA repeats³⁻⁷. Most of this length heterogeneity is generated by insertions at a specific site in the 28S gene³⁻⁷. The frequency and size patterns of these insertions in the 28S gene differ in the X and Y chromosomes^{4,7,8}. Electron microscopic analysis of rDNA-rRNA hybrids has shown that there is also length heterogeneity in the rDNA non-transcribed spacer^{4,6,7}. This heterogeneity is due in part to internal sequence repetition^{7,9}. We have now examined further the length heterogeneity of the rDNA spacer and have observed a class of spacers that we shall refer to as 'long spacers'. The size and frequency of these long spacers are different in the X and Y rDNA.

The resistance of the rDNA spacer to digestion with the endonuclease *Hae*III (ref. 10) provides a convenient method for the analysis of rDNA spacer size. To determine the spectrum of spacer sizes on the X and Y chromosomes, DNA from X/X or *sc*⁴-*sc*⁸/Y flies was digested with *Hae*III. (*sc*⁴-*sc*⁸ is an X chromosome that is at least 90% deficient in rDNA¹¹.) The resulting fragments were separated by agarose gel electrophoresis and subsequently transferred to nitrocellulose filters by the method of Wahl *et al.*¹², a modification of the Southern technique¹³, which increases the efficiency of transfer of large DNA fragments. The filter-bound fragments were hybridised to ¹²⁵I-labelled spacer DNA¹⁴ and finally visualised by autoradiography. The results of this experiment are shown in Fig. 2. In addition to the expected bands at 4-7 kilobases⁶, fragments at 11, 14 and 20 kilobases are apparent. We shall refer to fragments longer than 9 kilobases as long spacer. To insure that these long spacer fragments were not a result of underdigestion with *Hae*III, the DNAs were redigested with 20-fold excess of enzyme. These experiments yielded patterns identical to those shown in Fig. 2. Digestion with *Hae*III of other samples of X/X and *sc*⁴-*sc*⁸/Y DNAs prepared from independently derived stocks also yielded patterns identical to those in Fig. 2.

To show that the long spacers are continuous with the rRNA structural gene rather than surrounded by other sequences, DNA restricted with *Hae*III was probed with ¹²⁵I-labelled rRNA. In this case, the autoradiographic signal arises from the small segment of 28S rDNA which remains attached to spacer after restriction with *Hae*III (see Fig. 1). Although the intensity of signal of the long spacer fragments was weaker than that observed using ¹²⁵I-labelled spacer DNA as probe, patterns almost identical to those shown in Fig. 2 were obtained. Thus, the pieces of DNA containing the long spacers also contain rDNA genes.

Fig. 1 Repeating unit structure of the ribosomal RNA gene in *Drosophila melanogaster*. The ribosomal gene consists of regions coding for 18S rRNA, 28S rRNA, a non-conserved transcribed (NCT) sequence and a non-transcribed spacer. Length heterogeneity occurs in the insertion (INS) in the 28S rRNA and in spacer sequences. The sites recognised by the restriction enzymes *Eco*RI and *Hae*III are indicated by arrows (↑) and arrowheads (▲), respectively. The map for *Hae*III is incomplete; however, there are no additional sites between the two sites shown¹⁰.

As shown in Fig. 2, digestion with *Hae*III generates different spacer fragment patterns for DNAs derived from X or Y DNA. In addition to the major bands at 5-6 kilobases, there are bands at 20, 11, 7.8 and 7.4 kilobases on DNA from the X chromosome. In DNA from the Y chromosome, bands appear at 14, 11, 5.7 and 5 kilobases and minor bands at 8.9, 7.6 and 6.4 kilobases. Densitometer scans indicate that most (~85%) of the spacer DNA from the X chromosome is 5.7 ± 1.9 kilobases long and that 9.8% makes up the 7.8- and 11-kilobase bands. These results agree with the data of Pellegrini *et al.*⁶, who found ~10% of spacer sequences between 7.5 and 11.5 kilobases and the remainder at 5.67 ± 1.92 kilobases. Their electron microscopic methods, however, would not have detected the 14- and 20-kilobase segments. Approximately 80% of the spacer from the Y chromosome is between 4 and 7.6 kilobases. As there are 200 rRNA genes per nucleolus² and assuming that each is linked to a spacer 5.7 ± 1.9 kilobases long, we estimate from the densitometer scans that there are about three copies of the 20-kilobase spacer fragment and five copies of the 11-kilobase fragment in the X chromosome nucleolus organiser. Similarly,

Fig. 2 *Hae*III restriction patterns of rDNA spacer in *Drosophila melanogaster*. DNA (2 µg) from *sc*⁴-*sc*⁸/Y male and ORE-R X/X female flies was digested with *Hae*III, separated on the same 0.7% agarose gel, transferred to a single nitrocellulose filter and hybridised to ¹²⁵I-labelled spacer (specific activity 4 × 10⁷ c.p.m. per µg) DNA and a 200-fold excess of purified unlabelled rRNA. (*sc*⁴-*sc*⁸ designates an X chromosome deficient in at least 90% of its rDNA¹¹.) The size in kilobases of bands from X and Y derived DNA is given on the right. The size of the large fragments was confirmed by electrophoresis through 0.4% agarose. Densitometer scans of the X/X and *sc*⁴-*sc*⁸/Y lanes and the area under each peak are shown on the far right.

Fig. 3 *In situ* hybridisation of ¹²⁵I-labelled spacer to *D. melanogaster* polytene chromosomes. As noted in these representative nuclei, all grains appear over the nucleolus (exposure, 3 days).

we calculate that there are about 8 copies of the 14-kilobase spacer fragment, and 16 copies of the 11-kilobase fragment in the Y chromosome rDNA cluster.

It is possible that the fragments which hybridise to spacer segments do so because they share homology with the spacer but are not actually part of the structure of rDNA. For example, they might cross-hybridise with centromeric satellite sequences. If so, *in situ* hybridisation of ¹²⁵I-labelled spacer to polytene chromosomes should detect the presence of such sequences elsewhere in the genome. As shown in Fig. 3, the ¹²⁵I-labelled spacer hybridises exclusively to the nucleolus. Even extreme over-exposure (15 d) revealed no grains consistently over any portion of the genome other than the nucleolus. Thus, most, if not all, of the spacer sequences, including the long spacer fragments, are part of the structure of the rRNA genes and are present in the nucleolus.

Electron microscopy and restriction enzyme analysis of cloned and uncloned rDNA repeat units have shown that the non-transcribed spacer is moderately heterogeneous in length (5.7 ± 1.9 kilobases)^{4,6,7} and probably consists mainly of repeated sequence elements^{7,9}. We have shown that spacers longer than 9 kilobases also occur in ribosomal DNA. The organisation of the long spacers has not been further examined and it is possible that in addition to spacer sequences, non-spacer elements such as insertion sequences also reside in these gene units. Although the sequences of the major class of spacers are very similar in the X and Y chromosomes⁷, our results indicate that there are clear size and frequency differences between the long spacers derived from the X and Y chromosomes.

The heterogeneity observed in the size and frequency of long spacer supports the contention of Tartof and Dawid⁸ that the rDNA genes on the X and Y chromosomes are maintained separately without genetic exchange. Two previous pieces of evidence also support this argument. Wellauer *et al.*⁷ and Tartof and Dawid⁸ have shown that type 1 (5 kilobase) inserts which are frequent in X rDNA are absent in Y rDNA, and Yagura *et al.*¹⁵ have recently demonstrated that the primary structure of 18S rRNA transcribed from X rDNA differs from that of Y rDNA. In the light of these observations, it seems unlikely that genetic exchange is responsible for the similarity of transcribed^{7,16} and spacer sequences. Selection pressures may instead have a major role in the parallel evolution of tandemly repeated genes in non-homologous chromosomes.

The presence of a small number of copies of long spacer sequences within the rDNA suggests that the rRNA genes are not organised as a simple tandem array of 200 repeating units. Rather, they may be grouped into subclusters separated from

each other by long spacer. Note that changes in rRNA gene number arising from rDNA magnification or reduction tend to occur as single stepwise increases or decreases of approximately 50 or 100 rRNA genes^{2,17}. On the basis of several experimental lines of evidence, it was initially proposed that rDNA magnification and reduction are driven by unequal sister chromatic exchange¹⁸. It is conceivable that such exchanges may occur at sites in long spacer DNA.

A *trans*-acting factor mediates inversion of a specific DNA segment in flagellar phase variation of *Salmonella*

Kazuhiro Kutsukake & Tetsuo Iino

Laboratory of Genetics, Department of Biology, Faculty of Science, University of Tokyo, Hongo, Tokyo 113, Japan

Inversions of specific DNA segments have been shown to be involved in regulating gene expression in several systems, and flagellar phase variation in *Salmonella* is one example. Strains of diphasic *Salmonella* species, such as *S. typhimurium*, possess two non-allelic structural genes, *H1* and *H2*, for flagellin, the component protein of flagellar filaments. One or the other is expressed in a bacterial clone. Lederberg and Iino¹ reported that the switch from the expression of one gene to that of the other was controlled by a genetic element linked to the *H2* gene and that the state of *H2* determined the flagellar phase of the bacterium. Simon *et al.*²⁻⁴ have shown that the expression of *H2* is controlled by a recombination which inverts a region of DNA containing an element necessary for the transcription of *H2*. We report here that prophages P1 and Mu produce a *trans*-acting cytoplasmic factor which mediates the inversion of a specific DNA segment in flagellar phase variation of *Salmonella*.

H1 and *H2* specify phase-1 and phase-2 flagellin, respectively¹. Genetic⁵⁻⁷ and biochemical⁸ studies have shown that *H2* constitutes an operon with *rh1* which specifies a repressor of the expression of *H1*. When the *H2*-operon is active (*H2*-on), phase-2 flagellin is synthesised and *H1* is repressed by the product of *rh1*. When the *H2*-operon is inactive (*H2*-off), *H2* and *rh1* are not transcribed and, thus, phase-1 flagellin is synthesised. The element which determines the state of the *H2*-operon is termed phase determinant (*PD*)⁹. It is adjacent to the *H2*-operon and regulates its activity by inversion²⁻⁴. This invertible segment consists of 800 base pairs of DNA². From genetic studies of a strain of *Salmonella abortusequi*, a species

Table 1 Effect of the exogenous *vh2*⁺ allele on the flagellar phase variation of the *vh2*⁻ strain

Plasmids	Swarm-forming ability on motility agar plates containing anti-flagella antisera			
	none	e, n, x	a	e, n, x + a
None	+	-	+	-
pCR1	+	-	+	-
pKK1200	+	+	+	-

The bacterial strain was KK1027, a *strA recA* derivative of SL23 (Fig. 1). The hybrid plasmid, pKK1200, contained a 3.75-kb DNA fragment of *Salmonella* inserted into the *EcoRI* site of pCR1 (ref. 19). This fragment containing the *vh2*⁺ allele, *PD*, and *H2* but not *rh1* was derived from pJZ200 (ref. 20). This *H2* gene specified e, n, x-flagellin. Plasmids were introduced into KK1027 by F factor-mediated transfer from *E. coli* cells harbouring F' factor and either pCR1 or pKK1200. Motility agar plates contained, per litre of distilled water: 7.5 g tryptone (Difco); 2.5 g NaCl (Nakarai) 2.5 g agar (Shoei). Antisera were prepared from rabbits immunised by flagella. For the motility tests, cells were inoculated on to motility agar plates and incubated at 37°C for 1 or 2 d. +, Motile; -, non-motile.

that changes phase at very low frequency, Iino¹⁰ showed that the *vh2* gene controls the change of state of *H2*, to which it is closely linked. Diphasic strains carry the *vh2*⁺ allele and change their flagellar phase at frequencies of 10⁻³ to 10⁻⁵ per bacterial division¹¹. Stable-phase strains carry the *vh2*⁻ allele and change their flagellar phase at frequencies lower than 10⁻⁷ per bacterial division¹⁰. Thus replacement of *vh2*⁺ by *vh2*⁻ results in stabilisation of the *H2*-operon in whatever state it is at the time of the replacement. A model for flagellar phase variation of *Salmonella* is summarised in Fig. 1.

Among the factors involved in regulating flagellar phase variation of *Salmonella*, *PD* acts *cis* to the *H2*-operon²⁻⁴. To determine whether the *vh2* gene acts in *cis* (and is therefore probably identical with *PD*) or in *trans*, a hybrid plasmid (pKK1200) containing the *vh2*⁺ allele was introduced into the *vh2*⁻ strain (KK1027). This strain was an *strA recA* derivative of the *S. abortusequi* strain SL23 (Fig. 1, ref. 8). It was fixed in phase-2 by the *vh2*⁻ allele and produced flagella antigenically characterised by the antigen e, n, x. The repressed phase-1 antigen type was a. As Table 1 shows, strain KK1027 carrying pKK1200 showed phase variation, producing some sub-clones with antigen e, n, x and others with antigen a. By contrast KK1027 carrying pCR1 or no plasmid failed to change its flagellar phase. The expression of the previously repressed chromosomal *H1* gene specifying antigen a shows that there is no *rh1* product in the cells concerned, and therefore that not only the plasmid-borne but also the chromosomal *H2*-operon is 'off'. Thus the plasmid-borne *vh2*⁺ gene seems to act in *trans*, to

Table 2 Effects of prophage P1 or Mu on flagellar phase variation of *vh2*⁻ strains

Host strains	Plasmids	Production of motile cells
KK1251	None	-
	P1CMclr100	+
KK1252	None	-
	F' lac ⁺	-
	F' lacI ⁺ ::Muc62	+

KK1251 and KK1252 were *galE* and *strA* derivatives of SJW1250 (Fig. 1), respectively. P1CMclr100 was a temperature-inducible mutant of P1 carrying a chloramphenicol-resistance element, Tn9 (ref. 21). Muc62 was a temperature-inducible mutant of Mu-1 (ref. 18). P1CMclr100 lysogens were prepared from KK1251 according to Rosner²¹. (Prophage P1 persists in the plasmid state²².) F' lac⁺ or F' lacI⁺::Muc62 factors were transferred, from *E. coli* strains harbouring either of them, to KK1252 according to Miller²³. For the motility tests, cells were inoculated on to motility agar plates and incubated at 30°C for 5 h. One hundred clones were tested for each experiment. +, Presence of motile cells; -, absence of motile cells.

facilitate the change of state of *PD*, a change that is thought to involve inversion of the segment containing the promoter region of the *H2*-operon. This indicates that the *vh2* gene specifies a cytoplasmic factor that catalyses the inversion of *PD* in the flagellar phase variation of *Salmonella* (Fig. 1).

Bacteriophage Mu DNA contains a 3,000-base pair sequence—the G segment—that can undergo inversion¹², apparently correlated with the formation of infectious phage particles^{13,14}. A similar invertible region has been found in bacteriophage P1 DNA^{15,16} and termed the C region¹⁷. The G segment of Mu445-5 (ref. 18) defective in a *trans*-acting factor for G inversion has been shown to be inverted by the inversion system of P1 (ref. 14). We examined whether the inversion systems of Mu or P1 could invert the *PD* of *Salmonella*.

Derivatives of a *vh2*⁺*H2*[−] strain of *Salmonella* (SJW1250, Fig. 1) were chosen as tester strains. SJW1250 was fixed in phase-2 by the *vh2*[−] allele and had no flagella because of a defect in the *H2* gene. Its repressed *H1* gene was intact and specified flagellin, characterised by antigen *gt*. If this strain changes its flagellar phase from *H2*-on to *H2*-off, *gt*-flagellin will be synthesised and, thus, the bacterium will become motile. Normally, it produces motile sub-clones at a frequency of 10^{−8}. Using this system, we showed that the strains carrying P1 or Mu as prophage produced motile sub-clones at a high frequency.

Table 2 shows that KK1251 (a *gale* derivative of SJW1250) carrying P1Cmclr100 and KK1252 (an *strA* derivative of SJW1250) carrying F'lacI^s::Mucts62 were both able to form spreading colonies (swarms) on motility agar plates. They all produced *gt*-flagella, as revealed by slide agglutination tests with anti-*gt* antiserum. These results indicate that the change of flagellar phase from *H2*-on to *H2*-off occurred in culture. So do they also change flagellar phase from *H2*-off to *H2*-on and manifest phase variation? If their flagellar phase oscillates between *H2*-on (not flagellated) and *H2*-off (flagellated), cultures must contain both motile and non-motile bacteria. Therefore, clones cured of phase must be fixed in whatever state, either motile or non-motile, they are in at the time of curing. Table 3 shows that this was the case. Phages were reintroduced into some of the resulting non-motile clones to exclude the possibility that they were non-motile mutants rather than clones fixed in *H2*-on. The lysogens also changed their flagellar phase from non-motile to motile. Thus flagellar phase changed between *H2*-on and *H2*-off in the *vh2*[−] strains carrying P1Cmclr100 or Mucts62. The rate of phase variation calculated from the results in Table 3 was higher than 10^{−2} per bacterial division in both lysogens. This value was greater than that of *vh2*⁺ strains (for example, 10^{−3} per bacterial division in *S. typhimurium*¹¹). To exclude the possibility that the factor catalysing the inversion of *PD* might be produced by the chloramphenicol-resistance element (Tn9) of P1Cmclr100, temperature-resistant, P1-sensitive, and chloramphenicol-resistant clones were isolated from KK1251 carrying P1Cmclr100. They must have Tn9 inserted in their chromosomes and have been free from phages. The resulting

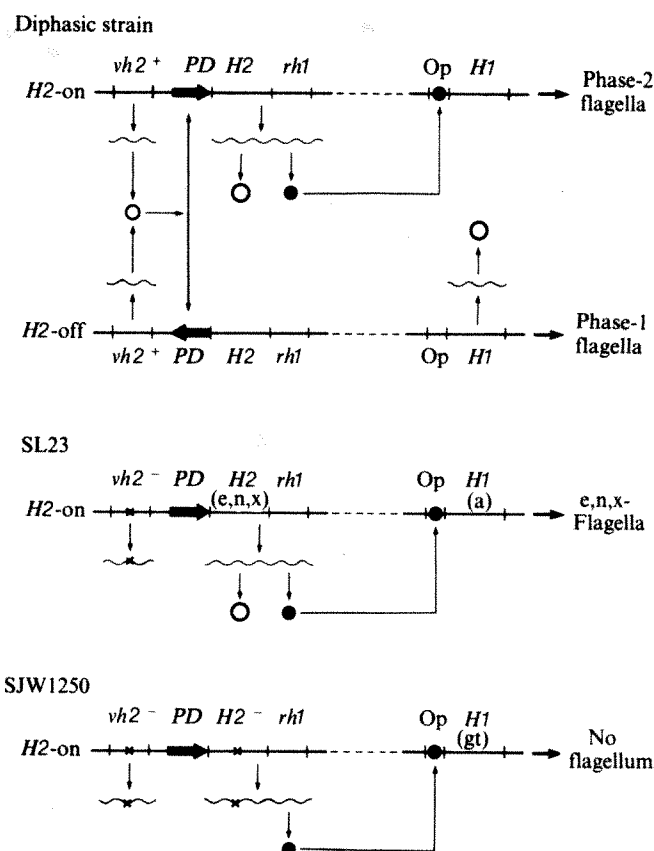

Fig. 1 Regulatory system for flagellar phase variation of *Salmonella*, diphasic strain, SL23 and SJW1250. *H1* and *H2* are structural genes for phase-1 and phase-2 flagellin, respectively. *H2* constitutes an operon with *rh1* which specifies the *H1*-repressor. *Op* indicates the binding site of the *H1*-repressor. *PD* indicates the phase determinant, which regulates the *H2* operon activity through a site-specific inversion. The *vh2* gene specifies a cytoplasmic factor which catalyses the site-specific inversion of *PD*. Horizontal heavy and wavy lines indicate the chromosomes of *Salmonella* and messenger RNA molecules, respectively. Large open and small closed circles represent flagellin and *H1*-repressor molecules, respectively. The small open circle represents the *vh2* gene product. Heavy arrows indicate the orientation of *PD*, which is expressed as the direction of transcription from a promoter residing in *PD*.

individual clones were also fixed in either the non-motile or motile state and did not change their flagellar phase (Table 3). Thus, P1 itself produces the factor catalysing the inversion of *PD*.

It is premature to conclude that the phase-specifying factor which catalyses the inversion of *PD* is also involved in the inversion of G segment in Mu or C region in P1. However, we have cloned the DNA fragment containing G segment of Mu or

Table 3 Flagellar phase of the *vh2*[−] strains cured of prophage P1 or Mu

Host strains	Plasmids	Selected phenotypes	No. of clones tested	No. of clones fixed in		Frequency of phase variation
				motile	non-motile	
KK1251	P1Cmclr100	tr	400	70	330	2.8×10^{-2}
		tr, Cm ^r	200	64	136	2.3×10^{-2}
KK1252	F'lacI ^s ::Mucts62	tr	260	140	120	1.5×10^{-2}

Motile clones harbouring either of the plasmids were grown in LB²³ at 30 °C for about 30 generations. Cultures of KK1251 harbouring P1Cmclr100 were diluted, plated on LB plates or LB plates containing 25 µg of chloramphenicol per ml, and incubated at 42 °C. The resulting isolates on the former plates were tested for P1 sensitivity and chloramphenicol resistance. All were P1-sensitive and chloramphenicol-sensitive and, thus, cured of P1Cmclr100. The resulting isolates on the latter plates were tested for P1 sensitivity, and all of them were found to be P1-sensitive. Thus, they carried Tn9 inserted on the chromosomes but no prophage. Cultures of KK1252 harbouring F'lacI^s::Mucts62 were diluted, plated on MacConkey lactose plates, and incubated at 42 °C. The resulting isolates were all found to form white colonies. For the motility tests, cells were inoculated on to motility agar plates and incubated at 42 °C for 5–24 h. Frequency of phase variation was expressed as the rate of change from motile (*H2*-off) to non-motile (*H2*-on) state per division of cells harbouring either prophage P1 or Mu. tr, Temperature-resistant; Cm^r, chloramphenicol-resistant.

C region of P1 on a plasmid vector, and KK1252 carrying the resulting hybrid plasmids also manifested phase variation (our manuscript in preparation). Thus it is highly plausible that such a factor also catalyses the inversion of G segment in Mu or C region in P1.

We propose that the genes whose products suppress the *vh2*⁻ allele of *Salmonella* should in general be termed *din*. In bacteriophage Mu, a gene which was thought to specify a *trans*-acting factor involved in G inversion was termed *gin*¹⁸. Because the *gin* gene was shown to be near the G segment¹⁸, the *din*⁺ activity of prophage Mu is probably specified by the *gin* gene. Enomoto and Stocker⁹ reported that when the *H2* locus of *Salmonella* together with the *vh2*⁻ allele was introduced into an

Escherichia coli strain by PI-mediated intergeneric transduction, the resulting transductants showed phase variation. This indicates that the *E. coli* strain also has a *din*⁺ activity, though *S. abortusequi* does not.

We thank Y. Komeda, S. Yamaguchi, M. Tsuda, and J. Roth for phages and bacterial strains, and M. Simon for a hybrid plasmid, pJZ200. All the experiments involving the construction and propagation of recombinant molecules were performed according to the 'Guidelines for Recombinant DNA experiments in Research Institutes such as Universities' (Ministry of Education, Science, and Culture, Japan, 31 March, 1979) in the P2 facility of our laboratory. This work was supported by a grant (410708) from MESC, Japan.

Many cyanobacteria fix atmospheric N₂ only in specialised cells called heterocysts^{1,2}. Besides containing nitrogenase², heterocysts are distinguished biochemically from vegetative cells by their inability to evolve O₂ or to perform photosystem II activities^{1,3,4} and by a deficiency in the CO₂ fixing enzyme ribulose-1,5-bisphosphate carboxylase⁵. These cells also lack phycobiliproteins and phycobilisomes, that are part of the major light-collecting system for the light reactions of photosynthesis^{1,6}. The phycobilipigments, light-collecting chlorophyll *a* and the photochemical reaction centres constitute a photosynthetic unit (PSU)—the minimum number of pigments necessary to drive photochemistry, oxygen evolution and photosynthetic electron transport. Therefore, the PSU represents an energy generating unit. In cyanobacteria, photosynthesis, and hence the PSU, contributes both ATP and probably a strong reductant to drive nitrogen fixation⁸. Because of the distinct photosynthetic properties of these cells, especially in pigmentation, we have compared the functional organisation of the pigments and photochemical activity of the thylakoid membranes from vegetative and heterocyst cells of *Nostoc muscorum* and *Anabaena cylindrica*. We demonstrate that the PSU is modified during the differentiation of heterocysts to support the specialised energetic requirements of these nitrogen fixing cells.

Axenic cultures of *A. cylindrica* (Cambridge culture collection no. 1403/2a) and *N. muscorum* (strain 7119) were grown in nitrogen-free medium as described previously⁸. Heterocysts and vegetative cells were separated, purified and counted⁸. The purified heterocysts (Fig. 1) were ruptured at 16,000 p.s.i. in a French pressure cell. Membranes were solubilised in Triton X-100 as described¹⁰ and PSU size measured¹¹ as the ratio of total chlorophyll to P700 (the reaction centre of photosystem I). The number of PSUs per cell was calculated from the cellular chlorophyll content and the PSU size¹¹. The spectral properties (300 and 77 K) of whole and detergent-solubilised membranes and fractions thereof were examined in an Aminco DW-2 spectrophotometer. Chlorophyll was determined in 80% acetone using the equations of Mackinney¹²; carotenoids were analysed using the methods of Davies¹³. Polyacrylamide gel electrophoresis of SDS-solubilised membranes was as described¹⁰ and distribution of chlorophyll in the pigmented gel zones was determined from gel scans¹¹.

To characterise the functional organisation of chlorophyll in the PSU of heterocysts and vegetative cells, spectral, photochemical and electrophoretic properties of Triton-solubilised membranes and the photosystem I reaction centre complex, the P700-chlorophyll *a*-protein, isolated therefrom were examined. In Triton-solubilised membranes of vegetative and heterocyst cells of both species, P700 photooxidation and dark reduction kinetics (see Fig. 2) were identical and indistinguishable from those described previously in other cyanobacteria and higher plants¹⁰. However, the wavelength of maximum absorbance decrease of P700 in Triton-solubilised membranes and the P700-chlorophyll *a*-protein occurred at 703 nm in contrast to 697 nm characteristic of P700 in higher plants and many cyanobacteria¹⁴. Previous investigations had demonstrated P700 in heterocysts by chemical difference spectra¹⁵ and by electron paramagnetic resonance spectroscopy¹⁶.

Thylakoid membranes from both cell types and species that were solubilised in SDS and electrophoresed in non-dissociating SDS polyacrylamide gels^{10,17} showed two pigmented zones. The slowest migrating zone was blue-green, stained for protein, and was identical in electrophoretic and spectral properties to the previously described SDS-altered form of the P700-chlorophyll *a*-protein or complex I. The second pigmented zone was green and did not stain for protein. It contained pigment, designated free pigment, that had been released from the native protein by detergent action. Complex I showed the same mobility in SDS gels and the same spectral properties whether isolated from

Table 1 Distribution of chlorophyll, PSU size and relative numbers of PSU/cell in vegetative and heterocyst cells of *Nostoc* and *Anabaena*

	Heterocysts	Vegetative cells
<i>Nostoc muscorum</i>		
Chlorophyll (μg per cell)	0.7×10^{-7}	1.4×10^{-7}
PSU size (chlorophyll/P700)	60	180
PSU per cell (molecules P700 per cell)	4.0×10^5	2.6×10^5
<i>Anabaena cylindrica</i>		
Chlorophyll (μg per cell)	0.9×10^{-7}	1.7×10^{-7}
PSU size (chlorophyll/P700)	60	180
PSU per cell (molecules P700 per cell)	5.0×10^5	3.1×10^5

Values are the average of at least three experiments.

vegetative or heterocyst cells independent of species. In the vegetative cells, complex I accounted for 20–30% of the total chlorophyll of the thylakoids while in the heterocyst cells it accounted for 70–80%.

Triton-solubilised membranes were used for the isolation of the P700–chlorophyll *a*–protein by hydroxylapatite chromatography^{10,17}. The absorption and photochemical characteristics of this complex isolated from the two cell types and species (Fig. 2) revealed an absorption maximum at 677 nm and a maximum absorbance decrease due to P700 at 703 nm. Only the P700–chlorophyll *a*–protein from *Anabaena* heterocysts showed the lack of a characteristic 490-nm shoulder in its absorption spectrum (Fig. 2). This shoulder has been attributed to β -carotene^{10,19}; indeed, thin layer chromatography of this isolated complex confirmed the absence of carotenoids. The P700–chlorophyll *a*–protein typically contains about 40 ± 10 chlorophylls per P700 in most species thus far examined¹⁴, and pre-

cisely that ratio in both cell types of *A. cylindrica* and *N. muscorum*. Thus, there seems to be no difference between the functional organisation of the centre of photosystem I in the different cells of the two cyanobacteria and that observed in other organisms.

Thylakoid membranes of both species solubilised in Triton X-100 revealed that vegetative cells have a similar chlorophyll to P700 ratio (180 ± 10) to that described previously for other cyanobacteria²⁰. Heterocyst thylakoids were more enriched in P700, exhibiting chlorophyll to P700 ratios of 60 ± 10 (Table 1). As heterocyst PSUs contain essentially no phycobilin pigments or phycobilisomes, the PSU size (ratio of total light-collecting tetrapyrrole chromophores to P700) in these cells is thus only about 60, compared to 300–350 (180 chlorophylls plus 120–180 phycobilin chromophores²⁰) in vegetative cells. Interestingly, the number of antenna molecules per reaction centre in heterocysts is the same small number found in many photosynthetic bacteria²¹. This large reduction in PSU size in heterocysts and the apparent enrichment of P700 is attributed both to the lack of

Fig. 2 Absorption spectra of the P700–chlorophyll *a*–proteins isolated from heterocyst thylakoids (at 20°C) of *N. muscorum* (---) and *A. cylindrica* (—). Insert shows kinetics of photooxidation and dark reduction of P700 from *A. cylindrica* heterocyst P700–chlorophyll *a*–protein determined as described previously¹⁰.

Fig. 1 *Nostoc muscorum*. *a*, Vegetative filaments showing terminal and intercalary heterocysts, the large, thick-walled cells. *b*, Isolated and purified heterocyst cells.

phycobilin pigments, and to a two-thirds reduction in chlorophyll *a*; it closely correlates with the lack of photosystem II (refs 1, 2, 4). Thus much, if not all, of the chlorophyll and all of the phycobilins normally associated with photosystem II in vegetative cells²² is lost during heterocyst differentiation. The loss of detectable photosystem II activity may be related to the lack of phycobilisomes or phycobilin pigments and perhaps of photosystem II chlorophyll–proteins.

In comparison to vegetative cells, *Nostoc* and *Anabaena* heterocysts contain half the chlorophyll content, but have a PSU containing only a third of the number of chlorophyll molecules (Table 1). In both species the number of PSU per cell (Table 1) is 35% greater in heterocysts than in vegetative cells. Therefore, heterocysts show a considerable increase in the cellular content of photosystem I, an ATP and reducing power producing unit. Previous EPR studies¹⁶ also have suggested an enrichment in both P700 and photosystem I bound iron–sulphur proteins in heterocysts. The present study allowed for a direct measurement of the photosystem I content per cell. An increase in photosystem I units should lead to enhanced rates of cyclic photophosphorylation. However, photophosphorylation in heterocysts has been reported to be lower than that found in vegetative cells⁴. Because of the impermeability of isolated heterocysts to reactants, photophosphorylation can be measured only in ruptured cells and this probably contributes to

the lower than expected activity. Hence, until an *in vivo* assay can be developed, it will be difficult to assess photophosphorylation rates in heterocysts accurately.

Several conclusions can be drawn from the present study concerning the relationships between the functional organisation of the PSU and photosynthetic activities, and the N_2 -fixing role of heterocysts. It is clear that heterocysts are capable of supplying sufficient ATP and reducing power to drive N_2 fixation. Although these cells have fairly high rates of oxidative phosphorylation², it has been demonstrated^{4,23} that photosynthesis is the principal energy source of ATP for driving N_2 fixation. Heterocyst differentiation, therefore, should lead to the development of a thylakoid membrane suited for the energetic requirements of the cell. That this is the case follows from several lines of evidence. First, differentiation of heterocysts from vegetative cells results in pigment losses which seem largely restricted to photosystem II. Consequently, photosystem

II activity is eliminated as is production of O_2 , a potent inhibitor of nitrogenase. Second, the pigment alterations lead to the construction of a much smaller PSU; this probably allows for packaging of greater numbers of units within a given cell volume. Third, the reorganisation of the photosynthetic apparatus results in a greatly increased number of photosystem I units which can function to produce ATP and reducing power to support the energetic requirements for N_2 fixation. Finally, the lack of ribulose biphosphate carboxylase eliminates a major competitive system for ATP and reducing power. Hence, the modifications in the photosynthetic systems that occur during heterocyst differentiation seem to be specifically geared to the energetic requirements of these cells.

Grasses more sensitive to SO_2 pollution in conditions of low irradiance and short days

Teresa Davies

Department of Biological Sciences, University of Lancaster,
Lancaster LA1 4QY, UK

Research into the effects of low levels of SO_2 on grasses has revealed no direct correlation between the dose of this pollutant and the plant's response¹. Authors have suggested that environmental factors are of prime importance in the control of the response, because in many cases damage was most severe during the winter^{2,3}. I have investigated the influence of total irradiance on the sensitivity of grasses to SO_2 , and shown that the effect of the pollutant was greatest in conditions of low irradiance and short photoperiod. Together, these factors may contribute to the increased sensitivity of plants during winter exposures to pollutants.

Experiments with a common pasture grass, *Phleum pratense* L. (Timothy), in a wind tunnel fumigation system had shown that plants grown at low irradiance, near the light compensation point, were more sensitive to 11 parts per hundred million (p.p.h.m.) SO_2 than plants grown under higher light levels (T.D., unpublished results). The experiment reported here was a continuation of that work, but irradiance levels and photoperiods representative of winter and summer conditions were used. Early in their growing season, grasses in Britain are exposed to days of about 12 h and low average irradiance, but during mid-summer, days of 16 h and higher levels of irradiance are experienced. Plants were therefore fumigated with SO_2 at these two day lengths, with a low irradiance of 40 W m^{-2} ($125 \mu\text{E m}^{-2} \text{ s}^{-1}$ photosynthetically active radiation, PAR), and higher irradiance of 130 W m^{-2} ($480 \mu\text{E m}^{-2} \text{ s}^{-1}$ PAR). Temperatures were the same for the two treatments, at 20°C (day) and 16°C (night), with a relative humidity of ~60%.

Seven-day old seedlings of Timothy variety S48 were fumigated in 'Perspex' chambers, volume approximately 0.08 m^3 , for

Fig. 1 Mean leaf area relative growth rates (\bar{R}_{LA}) for *Phleum pratense* L. with 12 p.p.h.m. SO_2 (----) or clean air (—). a, High irradiance, long day length; b, low irradiance, short day length.

5 weeks. Each chamber, containing 15 plants each in 7.5-cm pots, received air from a compressor at a rate of one complete air change per minute. In addition, a mixing fan situated inside the chamber rapidly circulated the air over the plants creating a turbulent wind speed of 0.4 m s^{-1} and good pollutant mixing.

NS, not significant.

Two chambers received 12 p.p.h.m. (343 $\mu\text{g m}^{-3}$) SO₂ continuously, and two received clean air containing 0–1 p.p.h.m. SO₂; these acted as the controls. A pollutant concentration of 12 p.p.h.m. is representative of several British urban areas in winter, and does not exceed the highest monthly mean concentrations recorded in Britain⁴.

Each week the plants were removed temporarily and leaf length and width were measured, so that mean relative growth rates of leaf area, \bar{R}_{LA} , throughout the experiment could be calculated (Fig. 1). There was a large difference in relative growth rates between the two light regimes, but the pollutant had no effect in high irradiance and long days. With low irradiance, however, there was a significant reduction ($P < 0.5$) of \bar{R}_{LA} between weeks 1 and 2, and weeks 3 and 4. This early interference in leaf growth could also be demonstrated by recording leaf lengths for the main shoot under low irradiance (Fig. 2). Little difference in leaf growth between SO₂ and control treatments was observed until after the second week of fumigation, when the first and second leaves had almost fully expanded. During the following weeks the senescence of these first two leaves was accelerated greatly by the presence of SO₂. The pollution also reduced the rate of extension of the third, fourth and fifth leaves, and reduced the mean maximum length of the third leaf. At harvest 5 there was no sign of the sixth leaf in the plants treated with SO₂, although in many of the control plants this leaf was quite well developed.

**Fig. 2** Changes in green leaf length of *Phleum pratense* L. with time under low irradiance, short day length, when exposed to 12 p.p.h.m. SO₂ (-----) or clean air (—).

After 5 weeks' fumigation, results of the final harvest clearly demonstrated an effect of SO₂ on plant growth in conditions of low irradiance and short days (Table 1). All shoot and root parameters show ~50% reduction in dry matter accumulation in SO₂, and the green leaf area was particularly affected, for leaf senescence was also promoted. In contrast, SO₂ had no significant effect on the rapidly growing plants grown in conditions of high irradiance and long days. Plants growing in these conditions seem to be particularly resistant to SO₂.

The environmental factors of irradiance and/or day length have therefore had a large effect on the sensitivity of *Timothy* to 12 p.p.h.m. SO₂. Consideration of the biochemical activity of SO₂ within the cell may help to explain this effect. SO₂ readily dissolves on moist cell surfaces to form sulphite ions, SO₃²⁻, and the dissociation products HSO₃⁻ and H₂SO₃, depending on pH. Excess SO₃²⁻ is thought to be toxic to the cell in several ways: it may increase acidity and cause breakdown of chlorophyll *a*, promoting senescence⁵; electron flow within the chloroplasts may be disrupted⁶; SO₃²⁻ may competitively inhibit ribulose biphosphate carboxylase activity with HCO₃⁻, reducing photosynthetic capacity⁷; it has also been suggested that SO₃²⁻ forms addition compounds with sensitive proteins⁸, and that the imbalance caused between partially oxidised and reduced S compounds may inhibit cell division⁹. However, when SO₃²⁻ enters the cell, a large proportion may be oxidised to less toxic SO₄²⁻. This is the usual form in which sulphur is supplied to the plant through the roots, and which is readily assimilated in the chloroplasts. The SO₄²⁻ is metabolised by the sulphate reduction pathway to produce amino acids such as cysteine, methionine and glutathione. This process requires ATP, reduced ferredoxin and amino acid skeletons, all of which would be plentiful in a plant growing in conditions of high illumination and adequate nutrition. However, plants whose growth is severely limited by light will have low reducing power and will not be able rapidly to detoxify SO₂ products along this pathway. Toxic levels of SO₄²⁻ and SO₃²⁻ are, therefore, likely to accumulate and growth may be inhibited.

In the field, plants rarely grow in ideal unstressed conditions. In the experiment reported here, irradiance and/or daylength restrictions have been shown to increase greatly the sensitivity to SO₂ pollution, and other factors of environmental stress are important. Plants, therefore, seem to be more sensitive to SO₂ in the low-growth conditions of the winter, which is also when pollutant concentrations are greatest. Because laboratory studies tend to be conducted in conditions favourable to growth, the impact of atmospheric pollution on vegetation could be much greater than many results have indicated.

I thank NERC for financial support, and Professor T. A. Mansfield for supervision.

Chemical constituents of host plants have been suggested to affect in part the ability of certain insects to produce sex pheromones, and thus their ability to reproduce¹. We have investigated such a relationship between the bark beetle *Ips paraconfusus* (Coleoptera, Scolytidae) and its host tree *Pinus ponderosa*. The pheromone system of the insect is well characterised^{2–4} and, as we report here, myrcene, a constituent of the host oleoresin system, is converted in the male beetle to its pheromones, ipsenol and ipsdienol. We used deuterium labelling techniques² to demonstrate for the first time the unequivocal conversion of a host plant chemical to an insect pheromone.

I. paraconfusus males feeding on host phloem tissue produce three terpene alcohols which together are attractive to both sexes—ipsenol (Fig. 1, III), ipsdienol (Fig. 1, II) and *cis*-verbenol. Myrcene (Fig. 1, I) was used because previous studies^{5,6} had indicated that ipsenol and ipsdienol were produced in male but not female beetles when exposed to this terpene.

Myrcene (I) was labelled with deuterium by an unambiguous synthesis at the positions shown to avoid loss of deuterium on conversion to ipsenol or ipsdienol. The oxidation products could be identified by gas chromatography–mass spectroscopy (GC-MS). Myrcene-D was prepared by the method of Westmijze *et al.*⁷. Reaction of 5-chloropent-2-one with methyl-magnesium iodide D₃ produced 5-chlor-2-methyl-pent-2-ol. The alcohol was dehydrated with powdered sodium bisulphite to give 4-methyl-pent-3-enyl chloride (*cis* and *trans* isomers). The latter compound was converted to its cuprate and then added to vinylacetylene to produce myrcene-D. The identity of the products at each step was confirmed by NMR and IR and mass spectral analyses. The NMR of myrcene-D (Perkin Elmer R32, 90 MHz) indicated a deuterium content of approximately 1.6D in the methyl groups at 1.45 and 1.37 p.p.m. No deuterium was observable in any other position. Gas chromatography in conjunction with electron impact and chemical ionisation mass spectroscopy (EI- and CI-GC-MS) confirmed the presence of an isomeric mixture of myrcene-D₃, -D₂, and -D₁ with myrcene-D₂ as the predominant isomer. The loss of deuterium was explained by exchange during the dehydration step.

Ten bark beetles of each sex were sealed in separate 20-ml ampules containing 10 µl of myrcene-D for 18 h as before⁶. Abdomens were then removed and crushed immediately in diethyl ether. Extracts were analysed by electron impact and chemical ionisation GC-MS on 10% Carbowax 20-m column using a Finnigan 4023 system. Peaks corresponding in retention time to ipsenol and ipsdienol, and possessing EI- and CI-GC-MS spectra consistent with the expected fragmentation patterns of ipsenol-D and ipsdienol-D, were observed in extracts of males, but not females. Further analysis by EI- and CI-GC-MS, using a SP-1000 30-m capillary column, confirmed the presence of the two deuterated compounds in male extracts which had coincident retention times with standard ipsenol and ipsdienol. With the exception of the diagnostic pattern of deuterium incorporation, the CI mass spectra of both compounds gave pseudo molecular ions (M+1) and fragmentation patterns similar to ipsenol and ipsdienol. The relative isotopic abundance of deuterium at M+1 for both compounds was also similar to that of deuterated myrcene. Clearly, these compounds were the hydroxylated products of labelled myrcene, deuterated ipsenol and ipsdienol.

Fig. 1 Structures of myrcene, ipsdienol and ipsenol. Asterisks indicate positions of deuterium.

We conclude that male *I. paraconfusus* can convert myrcene, a terpene hydrocarbon from its host plant, to its pheromones, ipsenol and ipsdienol. Moreover, the presence of other labelled metabolic products in both sexes and the absence of labelled ipsenol and ipsdienol in the female demonstrate the sexual specificity^{2,6} of the biosynthesis of the pheromones. Although we cannot rule out completely alternative pathways (such as *de novo* pheromone biosynthesis, the conversion of other terpene hydrocarbons to pheromones, or induction of pheromone secretion), our results coupled with the observation by Hughes^{5,8} and Byers *et al.*⁶ that ipsenol and ipsdienol are found only in *I. paraconfusus* males exposed to myrcene, support the primacy of host chemicals in pheromone production. If Renwick's demonstration of enantiomeric specificity⁹ in the production of *cis*-verbenol (the non-sex specific component of the pheromone of male *I. paraconfusus*) on exposure to (–)- α -pinene is also a direct biosynthetic step, then all three known pheromone components may be derived from the host plant by simple oxidation of available chemicals. Experiments with isotopically labelled (–)- α -pinene may provide support for this premise. Thus, the evolution of host plant preferences in bark beetles may be a consequence in part of the chemistry of the tree as it affects pheromone biosynthesis.

Transitorium 3, Padualaan 8, De Uithof, 3508 TB Utrecht,
The Netherlands

Lysophospholipids have been implicated in a variety of physiological processes¹. *In vivo* lysophospholipids are invariably produced with fatty acids as the product of hydrolysis by phospholipase A₂ (ref. 2). Therefore, it is of considerable interest to examine the properties of the mixture of these lipids in aqueous suspensions. Results presented here demonstrate that a mixture of fatty acid and lysophosphatidylcholine forms a bilayer type of organisation even though the individual components form micelles when dispersed in an aqueous phase.

1-Acyl-lysophosphatidylcholines were prepared by the action of phospholipase A₂ on phosphatidylcholines in moist diethyl ether. Dispersions of appropriate lipid mixtures were prepared by a standard procedure that is used for the preparation of phospholipid liposomes³ and described in Fig. 1. Freeze-fracture electron microscopy was carried out according to well established techniques⁴. Glycerol was added to the samples to prevent freeze damage.

The aqueous dispersions of lysophosphatidylcholines with various fatty acids are cloudy. When inspected under a polarising microscope they exhibit birefringence, and a flow birefringence can be seen even at less than 10 μ M. Neither of these components dispersed in water alone exhibits such a behaviour^{5,6}. The most distinctive behaviour of mixtures of lysophosphatidylcholine and fatty acid in an aqueous phase is seen in their thermotropic transition profiles. As shown in Fig. 1 the equimolar mixtures of palmitoyl lysophosphatidylcholine with the various fatty acids exhibit a twin endothermic transition at characteristic temperatures that depend on the nature of the fatty acid. Thus, for homologous fatty acids the transition temperature and the enthalpy of transition increase monotonically with the chain length. Other data (not presented here) demonstrate that the transition temperature is lower for the mixtures containing fatty acids with double bonds, such as elaidic and oleic acids. Also, incorporation of cholesterol in equimolar ratios to lysophosphatidylcholine and fatty acids abolishes the transition completely, and substitution of the fatty acid by a long chain alcohol such as *n*-hexadecanol exhibits a twin transition at 327 K (7.45 Kcal mol⁻¹). Such observations demonstrate that the phase transition properties of these mixtures are predominantly governed by acyl chain interactions.

The birefringence and thermotropic phase transition behaviour of lysophosphatidylcholine and fatty acid mixtures suggests the existence of a bilayer-like phase that undergoes a cooperative phase transition. This is confirmed by ³¹P-NMR and freeze-fracture electron microscopy. The ³¹P-NMR spectra over a wide temperature range (one of these spectra is presented in Fig. 2) exhibit asymmetric peaks typical of a bilayer type of lipid organisation⁷. The effective chemical shift anisotropy (CSA_{eff}) is reduced compared with that for phosphatidylcholines. This is not uncommon for lysophosphatidylcholine present in bilayers of other lipids (unpublished observations). Furthermore, the CSA_{eff} is apparently temperature dependent, becoming less at higher temperatures, although a bilayer type of organisation is retained over the 277–327 K range we have examined. As shown in Fig. 3, the freeze-fracture faces obtained on the

Fig. 1 The DSC scans of equimolar mixtures of palmitoyl lysophosphatidylcholine (LPC) with the fatty acids indicated as label: 12:O-, lauric; 14:O-, myristic; 16:O-, palmitic; 18:O-, stearic. The scans of palmitoyl lysophosphatidylcholine and dipalmitoyl-phosphatidylcholine (broken line) are given for comparison. The experimental details are presented in the text. The transition temperatures and enthalpy for the various mixtures are: LPC (278 K, 3.6 kcal mol⁻¹); DPPC (314.6 K, 8.7 kcal mol⁻¹); LPC+12:O- (297 K, 3.3 kcal mol⁻¹); LPC+14:O- (307 K, 5.0 kcal mol⁻¹); LPC+16:O- (315.3 K, 5.7 kcal mol⁻¹); LPC+18:O- (324 K, 6.7 kcal mol⁻¹); LPC+elaidic acid (302 K, 4.7 kcal mol⁻¹); LPC+oleic acid (290 K, 4.5 kcal mol⁻¹). Appropriate amounts of lipids mixed in chloroform solution were dried under vacuum and then dispersed by vortexing in an aqueous buffer containing 50 mM KCl and 40 mM Tris at pH 8.0 in 25% aqueous ethylene glycol (v/v). Differential scanning calorimetric profiles were determined on 15- μ l samples containing 3 μ mol lipid mixture in sealed aluminium pans on a Perkin-Elmer DSC-2 instrument. The scan range for all runs was 240–340 K, and the scan rate was typically 5 K min⁻¹. Lower scan rates, repeated heating and cooling scans, and dispersions containing no ethylene glycol gave essentially identical results.

dispersions support the existence of vesicular structures of 1,000–6,000 Å diameter. Their fracture planes suggest the presence of bilayer orientation similar to that present in diacyl-phosphatidylcholine dispersions.

The phase properties of palmitoyl lysophosphatidylcholine and fatty acid dispersions in water closely resemble the phase properties of diacylphosphatidylcholines containing similar chains. Such a similarity could result if the acyl chains of lysophosphatidylcholine and fatty acid molecules associate to

Fig. 2 The 36.4-MHz, high-power proton noise-decoupled ³¹P-NMR spectrum of an equimolar mixture of palmitoyl lysophosphatidylcholine and palmitic acid in 150 mM KCl, 10 mM Tris and 0.2 mM EDTA at pH 7.5 and 314 K. The spectrum was recorded using a spectral width of 12 kHz, 45° radio frequency pulses with pulse rate of 0.17 s and an exponential multiplication resulting in 50 Hz line broadening.

form a complex that resembles diacylphosphatidylcholine, that is, in bilayers phosphatidylcholine may be considered as a conformationally and orientationally restricted analogue of fatty acid and lysophosphatidylcholine⁹. Although such a concept does not necessarily imply formation of a strong association complex, it is useful in explaining the behaviour of mixed lipid systems^{8,9} as well as the properties of bilayers modified by various solutes³.

A distinct phase behaviour of lysophosphatidylcholine and the fatty acid mixture is also observed in bilayers containing diacylphosphatidylcholine. Studies on aqueous dispersions of the ternary mixture containing equimolar lysophosphatidylcholine and fatty acid with varying mole fractions of diacylphosphatidylcholine (data not presented here) exhibit phase separation over a wide concentration range. Once again the behaviour of the mixture is quite distinct from that of diacylphosphatidylcholine containing either lysophosphatidylcholine or fatty acid⁶.

Fig. 3 Electron micrograph of the freeze-fracture replica of dispersions of palmitoylphosphatidylcholine with palmitic acid (1:1) $\times 50,000$.

The full implications of a distinct phase behaviour of fatty acid and lysophosphatidylcholine mixture are under investigation. However, the observations reported here do provide for the first time a physical basis for several yet unexplained observations: certain cell types and organelles have considerable amounts of lytic lysophospholipids but remain viable¹⁰. This could be due to the presence of equimolar proportions of fatty acids as demonstrated for adrenal chromaffin granules (R. Franson *et al.*, in preparation). The latency period during the action of phospholipase A₂ on bilayers is abolished in the presence of both the products of hydrolysis but not by either one of the products alone (unpublished observation). A distinctive behaviour of such ternary mixtures is probably best manifested by the bilayers and biomembranes treated with phospholipase A₂. For example, almost all the phospholipid in the outer monolayer of a bilayer can be hydrolysed with phospholipase A₂ without disrupting the vesicular structure¹¹; the red cells treated with phospholipase A₂ lyse only when they are treated with bovine serum albumin¹², which presumably extracts fatty acids from the membrane, and ³¹P-NMR spectra of phospholipase A₂-treated erythrocyte membranes exhibit retention of bilayer organisation¹³. Such observations suggest that lysophosphatidylcholine and fatty acids together retard haemolysis. Indeed, in the presence of fatty acids the time for lysophosphatidylcholine-

induced lysis is prolonged several hundredfold, and unsaturated fatty acids are more effective than the saturated fatty acids.

We thank Mrs J. Leunissen-Bÿvelt for the electron microscopy work.

Counting integral numbers of amino acid residues per polypeptide chain

Thomas E. Creighton

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Proteins have integral numbers of each of the 20 amino acids. However, all the currently accepted methods of determining this number measure the ratio of moles of amino acid residue per mole of protein. This value is rarely close to an integer, due to experimental errors in determination of the molar amounts of both amino acid residues and polypeptide chain¹⁻³. A simple method which gives integral values of amino acid residues per polypeptide chain, independent of any other properties of the protein, would be useful in characterising proteins. We describe here one method; it is illustrated for the case of Cys residues, although the approach should be useful for many of the other 19 usual amino acids.

The method relies on the charge differences introduced by specific chemical modification of the amino acid. In Cys residues this is readily accomplished by reaction of the thiol group with iodoacetic acid, which introduces acidic carboxymethyl groups. Because of the chemical reactivity of thiol groups, Cys residues not reacted with iodoacetate are blocked with iodoacetamide, a similar, but uncharged, reagent.

A complete spectrum of protein molecules having 0, 1, 2, ..., n acidic carboxymethyl groups, where n is the integral number of Cys residues per protein molecule, is generated by reacting all the thiol groups with varying ratios of iodoacetamide to iodoacetate, using competition between the neutral and acidic reagents. To make all thiol groups of the protein chemically equivalent, the reaction is carried out in denaturing conditions, in this case, in 8 M urea.

The molecules with varying numbers of acidic groups are separated by an appropriate method; here by electrophoresis in conditions where the electrophoretic mobility is determined by the net charge of the protein. The number of species ($n + 1$), and hence the number of Cys residues (n), is determined by counting the number of bands.

The procedure is shown in Fig. 1a with bovine pancreatic trypsin inhibitor (BPTI), a small protein known to have six Cys

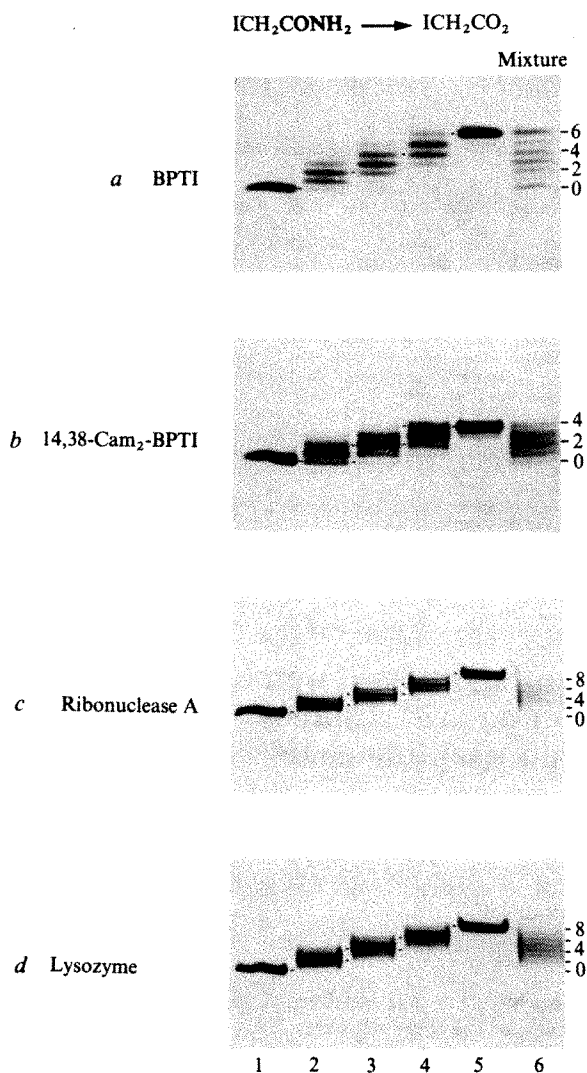

Fig. 1 Electrophoretic separation of protein molecules with 0 to n acidic carboxymethyl groups, where n is the number of cysteine residues in the protein. The reduced proteins were reacted with the neutral iodoacetamide (channel 1, on left), acidic iodoacetate (channel 5), and 1:1, 1:3, and 1:9 ratios of neutral to acidic reagents in channels 2, 3 and 4, respectively. Channel 6 (right) contains a mixture of equal portions of the samples applied to channels 1–5 in *a*, and of channels 2–4 in *b*, *c* and *d*. The bands are counted on the right by the number of acidic groups, and even-numbered bands are connected by dashes between them. The proteins (0.2 mg) were reduced and unfolded by incubation at 37 °C for 30 min in 1.0 ml 8 M urea, 10 mM dithiothreitol, 10 mM Tris-HCl, 1 mM EDTA, at pH 8.0. They were then alkylated by adding 200 μ l of this solution to 50 μ l of 0.25 M iodoacetamide, iodoacetate (adjusted to pH 8.0 with KOH), or mixtures of the two; after 15 min at room temperature, the solutions were placed on ice. Portions of 50 μ l were placed on polyacrylamide gels containing 8 M urea, using the low-pH discontinuous system of Reisfield *et al.*¹⁷; electrophoretic separation was at constant current (100–160 V) at 3 °C for 3–4 h. Staining was with 0.1% (w/v) Coomassie brilliant blue in 10% (w/v) trichloroacetic acid and 10% (w/v) sulphosalicylic acid overnight. The gels were destained by diffusion into 7.5% acetic acid and 5% methanol.

residues^{4–6}. The reduced protein in which the six thiol groups were blocked with iodoacetate migrates electrophoretically more slowly than that blocked with iodoacetamide, due to the six acidic carboxymethyl groups⁷. Reaction of the six thiols with mixtures of the neutral and acidic reagents in three different ratios generated the seven bands expected with six cysteine residues. Approximately equal competition between the two reagents was observed with a ratio of iodoacetate to iodoacetamide of 3:1, indicating that the latter reacts three

times as readily as the former, as has also been observed by others⁸. This mixture produced primarily molecules with 2, 3 and 4 carboxymethyl groups, so the entire spectrum was generated with threefold lower and higher ratios of reagents to generate significant amounts of molecules with 0, 1, 5 and 6 acidic groups. Molecules with 0 and 6 acidic groups were observed when the protein was reacted with just iodoacetamide and iodoacetate, respectively. All seven bands could be demonstrated simultaneously by making a mixture of the above populations.

BPTI, in which two Cys residues (residues 14 and 38) had been blocked covalently by iodoacetamide before competitive modification as described above, so that only four Cys residues were present^{9–11}, gave the expected five bands (Fig. 1*b*). Reduced bovine pancreatic ribonuclease and hen egg lysozyme, each with eight Cys residues^{12,13}, gave the expected nine bands in both instances (Fig. 1*c*, *d*). Bovine α -lactalbumin and β -lactoglobulin clearly demonstrated the presence of eight and five Cys residues, respectively, using an electrophoretic system for acidic proteins. Proteins with no Cys residues, such as the penicillinase of *Staphylococcus aureus*¹⁴, gave only a single band in all instances, with the same mobility when treated with either iodoacetamide or iodoacetate.

The procedure developed here for Cys residues is simple, rapid and gives integral values of the number of cysteine residues per polypeptide chain, independent of any other information about the protein, including its molecular weight. The procedure should be useful in determining the number of Cys residues of other proteins. It requires only a nearly homogeneous preparation of protein (which is also necessary, although not sufficient, for the determination of a correct value using currently accepted procedures) and a method of separating molecules with different numbers of carboxymethyl groups. The separation of species could be enhanced by the use of competition between acidic (iodoacetate) and basic (for example, ethyleneimine)¹⁵ reagents. Other means of separating such species, such as isoelectric focusing or ion-exchange chromatography, may be more appropriate with other proteins.

The general approach should also be useful for counting other amino acid residues for which there are specific reagents to introduce differences in net charge or other properties that may be used to resolve the species. Only a single reagent need be used, and the spectrum of molecules with 0 to n residues may be generated by varying either the time of reaction¹⁶ or the concentration of the reagent. Where two or more different reagents are available, competition between them may be used, as with iodoacetamide and iodoacetate here. The reaction should be carried out in conditions where the protein is unfolded and where all residues of the protein react at similar rates with the reagent. That this was the case with the Cys residues of the proteins studied here¹⁶ is demonstrated by the close agreement of the distributions of molecules with different numbers of carboxymethyl groups with distributions expected to random reaction of each of the Cys residues with the neutral and acidic reagents. The species generated must also be separated in unfolding conditions, where the modified residues have an equivalent effect on the separation procedure. For example, the band of BPTI with one carboxymethyl group per molecule contains molecules in which that acidic group is on any of the six Cys residues of the protein¹⁶, so all six isomeric species must have the same electrophoretic mobility. The other bands must also contain large numbers of species with the carboxymethyl groups distributed over the six Cys residues. Yet the bands are as sharp as those of the homogeneous species with 0 and 6 carboxymethyl groups and are equally spaced.

Any such modification procedure will depend on the selectivity of the reagent and on obtaining stoichiometric reaction of the residues of the pertinent amino acid in limiting conditions, which should be apparent by comparison of the mixtures at varying extents of reaction. Stoichiometric reaction should be indicated by approaching formation of a single species after extensive reaction, as is the case in Fig. 1. Slower reaction at

other sites should be apparent by the slower generation of additional, multiple bands after very extensive reaction.

The procedure developed here will not replace the standard methods of amino acid analysis, as it is unlikely that specific methods will be available for specifically modifying those amino acids with no reactive groups, for example glycine, proline, valine, leucine. Nevertheless, it should be useful for calibrating the molar ratios determined by amino acid analysis, using the integral values determined for one or a few convenient amino acids.

Bayer provided purified BPTI (Trasylol). We thank Miss Denise Thomas for assistance and R. H. Pain for supplying *Staphylococcus aureus* penicillinase.

Brillouin scattering, density and elastic properties of the lens and cornea of the eye

J. M. Vaughan

Royal Signals and Radar Establishment, St Andrews Road, Great Malvern, Worcester, UK

J. T. Randall

Department of Zoology, University of Edinburgh, West Mains Road, Edinburgh, UK

Brillouin spectra of biological systems may ultimately be related to their intrinsic molecular properties. In some instances the optical properties may be associated with the elastic ones and ultimately with the force constants of the molecules involved^{1,2}. In the present work we have used a triple-pass Fabry-Perot interferometer to measure Brillouin light scattering spectra for refractive tissues of the eye, including cornea, capsule and lens. Combined with corresponding measurements of density, estimates of the real and imaginary parts M' and M'' of the longitudinal bulk modulus have been made for the first time. Measurements have extended over four classes of vertebrate: Mammalia, Aves, Pisces and Amphibia; only small differences have been found between the various samples of cornea, whereas marked differences occur between the different lenses. Hence this account concentrates largely on the latter. The implications of this work lie not so much at the ophthalmological level as at the macromolecular and offer, in conjunction with other scattering techniques, opportunities for probing the lens and its proteins topographically as a function of growth.

The development, morphology, biochemistry, optics and vision of normal vertebrate eyes have been studied for many years³⁻⁷, but comparatively few investigations of the elastic

properties of lenses have been made and none by the method presented here⁸⁻¹⁴.

Brillouin scattering^{15,16} arises when light is scattered by the periodic fluctuations in density that occur in condensed matter as a result of thermally excited hyperfrequency sound waves. The scattered light is shifted in frequency from that of the incident light by typically 1-10 GHz for 90° scattering because of the interaction of the incident light waves with the coherent longitudinal sound waves. The simplest Brillouin spectrum of an isotropic substance therefore consists of the central unshifted Rayleigh line together with two satellites of lower and higher frequency respectively. Aqueous gels of low macromolecular content (~1% by weight) will give Brillouin shifts differing only slightly from that of water, whereas gels of high protein content lead to substantial shifts (ref. 17 and our unpublished data). The high protein content of corneal and lens tissues makes them particularly suitable for the present measurements.

From the differential equation governing the propagation of a longitudinal acoustic wave in a viscoelastic medium the complex longitudinal modulus M^* is given by¹⁸

$$M^* = M' + iM'' = \rho u^2 + i(2\rho u^3 \alpha / \omega) \quad (1)$$

whence

$$M' = \rho u^2 \quad (2)$$

and

$$M'' = 2\rho u^3 \alpha / \omega \quad (3)$$

where ω is the angular frequency of the shift, u the speed of hypersound in the medium α the attenuation defined by the relation

$$\Delta = \alpha u / \pi \quad (4)$$

where Δ is the corrected width of the Brillouin line (FWHM in GHz).

In the arrangement used in these experiments^{2,19} the Brillouin shift Ω is related to the hypersonic speed and the wavelength of incident radiation λ_0 by

$$\Omega = \pm 2n_1 \frac{u}{\lambda_0} \sin \beta \quad (5)$$

when n_1 is the refractive index of air and 2β the scattering angle in air ($90^\circ \pm 1^\circ$).

Provided the density of the sample is known one can therefore determine the longitudinal compressive moduli M' and M'' from measurements of Brillouin scattering data. Characteristic results are summarised in Fig. 1A and B and Table 1.

Collection of data on the lens of the normal human eye has been limited by scarcity of suitable material. The spectra shown in Fig. 1A were taken from one of the two globes so far made available to us and at a time before the development of the density-measuring technique (see legend to Table 1).

The Brillouin shift observed for corneal material, ~4.5 GHz, is lower than that for rat-tail collagen^{1,2}. This is almost certainly due to the fact that the cornea is a complex tissue of collagen, proteoglycans and water. All biological specimens so far examined (including bovine serum albumin, data not shown) show marked increases in Brillouin shift on drying.

Before discussing the data on lenses summarised in Table 1 it is important to note the mode of development through the differentiation of their epithelial cells. Elongated cells are produced at the cortex; and as new layers are formed older ones move inwards. In man and primates this leads to a lens structure of concentric layers of closely apposed fibre cells. In general, the protein content, density and refractive index of the lens increases along any radial line joining periphery to centre. The lens is in broad terms a complex protein gel, the overall protein content of which is about one-third of the lens mass. The chief proteins of the mammalian lens are known as the crystallins, which are globular in character and comprise four predominant classes α , β , γ and δ . Each class contains a number of separable

proteins. Of these the γ class is a closely similar group of cryoprotein monomers of low molecular weight ($\sim 20,000$), while the α and β crystallins (with the exception of β_s) are heteropolymers. The distribution, proportions and molecular weights of the crystallins in the lens change during development as new fibres of different composition are laid down.

Turning to Table 1 and Fig. 1, it is clear that in all lenses studied so far values of density, hypersound speed and elastic modulus (as here defined) all increase from the lens periphery to the centre of the nucleus. This is consistent with Bettelheim and Wang's²⁰ corresponding observations of topographic variation of refractive index in the lens of the calf. In man, cow and sheep there are comparatively small changes of lens density and Brillouin shift between periphery and nucleus. This contrasts sharply with the case of the rat for which a nuclear Brillouin shift of ~ 8.8 GHz has been observed. The quasi-spherical lens of the rat is also substantially different in shape from the generally oval character of those found in the other mammals investigated. The lens of the fowl is rather soft and there is not much difference in elastic modulus between periphery and nucleus. With the bony fishes we come again to lenses almost spherical in shape and with very hard nuclei with appropriately high values of M' . The data for *Sarotherodon mossambicus* (Fig. 1B) and *Perca fluviatilis*

(Table 1) are typical in showing high Brillouin shifts for lens nuclei which are always physically more obvious than in the mammals (other than rodents) and the fowl.

It is interesting to compare the present values of M' of about $3 \times 10^9 \text{ N m}^{-2}$ with the values of Young's modulus for the human lens measured by Fisher^{8,9}. For essentially static distortions values of $3 \times 10^3 \text{ N m}^{-2}$ for the lens and 10^6 N m^{-2} for its isolated capsule were found. We should emphasise that our own values relate to a microscopic scale and that the light scattered is effectively probing high frequency sound wave propagation at wavelengths $< 1 \mu\text{m}$ which is smaller than recorded measurements of lens fibre width. Note that in his lens measurements Fisher takes an average value for lens density, whereas in our work values for small volumes of tissue are measured at positions corresponding to the recorded Brillouin shifts. Our values of longitudinal bulk modulus (M') are of similar magnitude to those found recently for collagen^{1,2}. Kikkawa and Sato¹¹ and Ejiri *et al.*¹² have not given values of the modulus and their results can thus not be compared with the present work.

Fisher and Pettet²⁵ have reported that the lens nucleus in man contains $63.4\% \pm 2.9\%$ water by weight and the cortex $68.8 \pm 4.3\%$. In some animals (Table 1) the nuclear density approaches that of crystalline proteins²⁶ where values of water content by

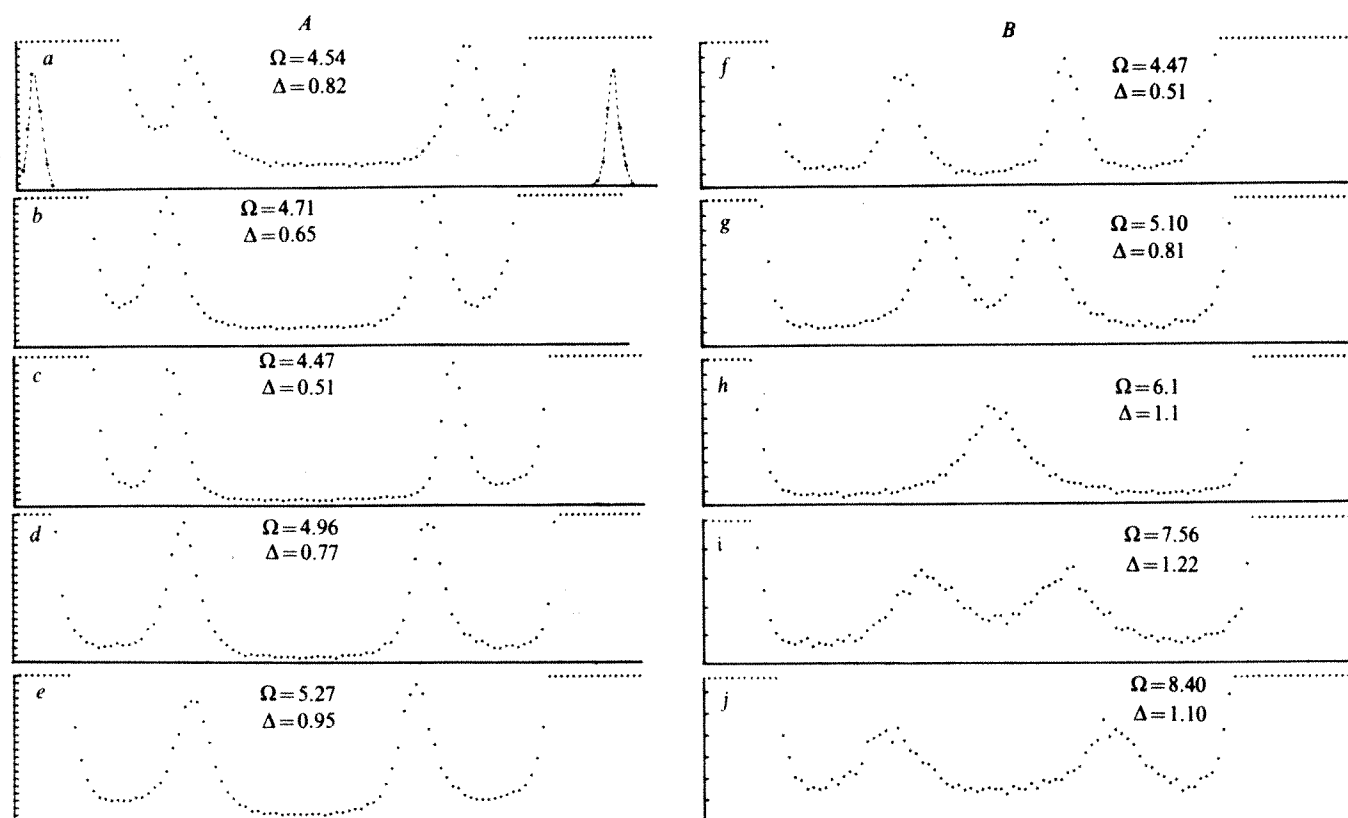

Fig. 1 Eyes were removed from animals within an hour of death and kept in liquid paraffin over ice until the material could be isolated for experiment. In these conditions the cornea and lens tissues showed little spectral change over a period of ~ 2 days. After removal from the globe, material was mounted between microscope slides separated by near-airtight spacers of different thicknesses, but usually $\sim 250 \mu\text{m}$. Samples of cornea were generally thicker than this and with a little Ringer solution gave a good optical seal to the slides and consequently good transmission of the incident laser beam. Two types of lens preparation were employed: either small excised portions $\sim 1 \text{ mm}^3$; or, where spherical as in fish and rat, the whole tissue. The slides were mounted as described previously^{2,19}. With this arrangement the refractive index is not required and the measurements are made at a constant scattering vector \mathbf{K} where $|\mathbf{K}| = (4\pi n_1 \sin \beta) / \lambda_0$ (here equal to $1.82 \times 10^7 \text{ m}^{-1}$). **A**, Brillouin spectra of eye material from man and sheep. The recordings show one complete order with free spectral range 17.0 GHz; instrumental peaks from elastic scattering are superimposed and shown dotted at the top (and greatly reduced). The Brillouin peaks are frequency shifted from their nearest elastic peak: *a*, human cornea (and instrumental peaks); *b*, periphery, human lens; *c*, capsule, sheep lens; *d*, periphery, sheep lens; *e*, nucleus, sheep lens. The lens of the human eye which was examined ~ 4 d post mortem showed a strong yellow fluorescence characteristic of age of subject and its rather cloudy appearance gave very strong elastic scattering. The full scale ordinate is 2,000 counts per channel and the channel width is 173 MHz; the measured shifts and reduced line widths (FWHM) in GHz are shown. **B**, Brillouin spectra recorded at different radial depths in one specimen of the spherical lens of the teleost fish *Sarotherodon mossambicus*. The lens diameter is $\sim 2.0 \text{ mm}$ and the free spectral range 12.2 GHz. The Brillouin shift increases sharply through the series from periphery to nucleus and the peaks in *i* and *j* relate to the further elastic peak. The depths are *f*, 0.06 mm; *g*, 0.28 mm; *h*, 0.52 mm; *i*, 0.76 mm; *j*, 1.0 mm (at lens centre). The measured shifts and reduced line widths (FWHM) in GHz are shown; the intervals on the ordinate scale are 100 counts per channel and the channel width is 122 MHz.

Table 1 Examples of Brillouin scattering, density and elastic moduli for eye tissues of Mammalia, Aves, Pisces and Amphibia

Animal	Tissue	Density ρ (kg m^{-3})	Brillouin shift Ω (GJz) Δ	Spectral width	Hypersound velocity (from equation (2)) u (km s^{-1})	Absorption coefficient $\pi\Delta/u$ ($\times 10^6 \text{ m}^{-1}$)	Longitudinal elastic modulus	
							M' ($=\rho u^2$) ($\times 10^9 \text{ N m}^{-2}$)	M'' ($=2\rho u^3\alpha/\omega$) ($\times 10^6 \text{ Nm}^{-2}$)
Cow (<i>Bos</i> sp.) (1 yr 9 months)	Cornea	1,107	4.43	0.87	1.52	1.8	2.56	5.1
	Lens: periphery	1,105	4.93	0.83	1.70	1.5	3.20	5.3
	Lens: nucleus	1,248	5.36	1.02	1.85	1.7	4.27	8.0
Rat (<i>Rattus</i> sp.) (19 weeks)	Lens: periphery	1,144	5.60	1.09	1.93	1.8	4.26	8.4
	Lens: nucleus	1,358	8.78	1.02	3.03	1.1	12.5	15
Bird Domestic fowl <i>Gallus</i> sp. (30 weeks)	Lens: periphery	1,082	4.61	0.51	1.59	1.0	2.73	3.0
	Lens: nucleus	1,124	4.91	0.61	1.69	1.1	3.21	3.9
Fish (teleost): perch <i>Perca fluviatilis</i> (~7 months)	Lens: periphery	1,103	4.93	0.59	1.70	1.1	3.19	3.8
	Lens: nucleus	1,238	8.75	1.09	3.02	1.1	11.3	14
Amphibian: common frog <i>Rana temporaria</i> (mature)	Lens: periphery	1,108	4.50	0.45	1.55	0.9	2.66	2.6
	Lens: nucleus	1,118	6.6	1.00	2.28	1.4	5.81	9.0

The passively stabilised triple pass interferometer²¹ used in these experiments was essential to bring out the weak Brillouin scattering features observed in the presence of strong elastic scattering at the incident frequency. The light source was an argon ion laser operating in a single mode at 488 nm and at power levels varying between 5 and 20 mw. For most of the material studied the Brillouin scattering intensity was comparable with that of pure water, and spectra with about a thousand counts per channel in each peak could be accumulated in about 10 min. Within the sample, the laser beam was focused to ~30 μm diameter and scattered light was collected from ~25 μm length along the beam, corresponding to a volume of $\sim 1.4 \times 10^{-4} \text{ mm}^3$. The corneas were found to become slightly cloudy within 12 h post mortem and very strong elastic scattering $\sim 10^6$ times the Brillouin scattering intensity was evident. Material from lens and capsule generally showed 1–2 orders less elastic scattering. A gradient density column (originally introduced by Linderström-Lang and Lanz²² as modified by Low and Richards²³) has been used to measure density using a mixture of xylene ($\rho = 865 \text{ kg m}^{-3}$) and chloroform ($\rho = 1,498.4 \text{ kg m}^{-3}$) in a small closed measuring cylinder coated internally with 'Repelcote' to prevent adherence of tissue. The preparation of the column and precautions required followed the lines of the earlier work and will not be elaborated here. Accurate measurements of density can readily be obtained in this way, but it is more difficult to determine precisely the position within the lens from which tissue has been removed and techniques are being developed to overcome this. The values of density given for nuclei are for the nucleus as a whole in rat, fish and frog; in other mammals and birds the specimen was excised from the centre. Attempts to fragment the denser nuclei by cutting slices frequently resulted in complete opacity and it cannot be assumed that the density in this state is normal. The calibration droplets of KBr solutions were checked with a Paar densimeter²⁴.

volume of ~43% occur most frequently and may range from 27 to 65%. In old rat lenses protein concentrations in the nucleus may reach values as high as 0.9 g ml^{-1} corresponding to a water content of only 35% by volume²⁷. The high values of Brillouin shift in certain lens nuclei thus seem to correlate well with high protein concentration and low water content.

Note that in weak gels at low concentrations the Brillouin scattering technique would measure hypersound wave propagation in the solvent, corresponding to $\sim 1,400 \text{ m s}^{-1}$ or $\sim 4.3 \text{ GHz}$. For low concentrations ($c \approx 1\%$) the essential propagation in the gel network is slow; speeds up to 10 m s^{-1} have been found by Brenner *et al.*²⁸ in agarose gels, with elastic moduli varying as $c^{4.1}$ (their equation (4)). A large extrapolation to concentrations of ~35% suggests a speed in the gel lattice of the order of that found for the solvent. This establishes that at even higher protein concentrations as in the lens nucleus the propagation must be essentially dominated by the gel and its structure.

In conclusion we have used Brillouin scattering to determine for the first time the longitudinal high frequency elastic modulus of a substantial variety of vertebrate lenses. This in combination with other scattering techniques summarised below offers an

additional approach to the study of the biophysics of lenses on a molecular scale.

The use of a range of incident light-wave frequencies and scattering vectors as well as variation of temperature would allow the investigation of dispersive effects in lens material and further clarify the differences between the static results of Fisher⁸ and our own dynamic studies. There is also some promise that the use of Raman spectra²⁹ may add precision to the knowledge of protein content and secondary structure in lenses as a function of position and development. X-ray diffraction studies of lens nuclei in particular may help to understand the properties of this high-density material. The use of individual crystallins of the vertebrate eye as model systems is now possible and makes the investigation of the effect of variation of water content on Brillouin spectra of lens proteins an important prospect.

We thank Karen M. Mundell for the measurements of density; R. M. Clayton and C. J. Randall for helpful discussions; and Professor M. S. Laverack, D. B. Marshall Ltd, D. H. Mills, Professor C. I. Phillips and Professor R. J. Roberts for material. J.T.R. is in receipt of a grant from the MRC.

MATTERS ARISING

A new tectonic model for the central Norwegian Caledonides

HORNE'S¹ recent model for the evolution of the central Norwegian Caledonides requires that the Storen, Hovin and Horg Groups originated as an intra-oceanic arc complex above a westerly dipping subduction zone. It is difficult to reconcile present knowledge of the volcanic and sedimentary rocks of these groups with this hypothesis. The Storen Group metavolcanics are well established as being ocean floor basalts² obducted onto the Baltic Shield in pre-Arenig times³. In the Løkken-Meldal region a younger complex of basic volcanics of late-Arenig age occurs within the Lower Hovin Group⁴. These are considered to have originated in a back-arc marginal basin situation⁵. Calc-alkali volcanics of similar age occur some 100 km further west³. The Lower Hovin Group locally contains meta-andesites, but these are volumetrically less important than the rhyolitic volcanics which predominate in the upper Lower Hovin, Upper Hovin and Horg Groups^{4,6,7} (mid-Ordovician to early Silurian). In the Løkken-Meldal region the volcanoclastic sandstones of the Lower Hovin Group have a quartz content that is considerably higher⁴ than that considered typical of an island arc environment⁸. The sandstones and shales of the Upper Hovin Group have a chemistry and mineralogy consistent with a rhyolitic/granitic (continental?) provenance (unpublished data). The Horg Group contains quartzites and vein quartz pebble conglomerates^{6,7}. Thus neither the volcanic nor the sedimentary rocks of the Storen, Hovin and Horg Groups are typical of those expected in an ensimatic arc complex. Indeed the presence of considerable rhyolitic volcanic products is

often considered to imply an Andean type margin^{9,10}. Also the distribution of late-Arenig vulcanism suggests an arc to the west with a marginal basin opening to the east—this requires subduction of the opposite polarity to that proposed by Horne¹.

HORNE REPLIES—Ryan has raised some important and difficult problems of provenance and petrogenesis that persist in other parts of the Appalachian-Caledonian orogen as well as in the Trondheim region. I look forward to evaluating the unpublished papers he cites as evidence, particularly those pertaining to the age of obduction and the polarity of subduction.

Many of Ryan's arguments are based on the composition of extrusive and detrital rocks in the Løkken-Meldal area some 60 km west of Selbusjøen. Although I have not studied those rocks I am reluctant to accept generalisations based on petrotextonic pigeonholing when it is well established that volcanics in modern arcs and even some spreading ridges are so variable in composition^{1,2}. The compositions of the volcanic and sedimentary strata that Ryan describes from the Løkken-Meldal area are similar to those of strata of comparable age exposed in the

Bronson Hill anticlinorium of New England^{3,4}. Rhyolites are common in the Ordovician volcanic succession, and they are thought to have been the original core rocks of the Oliverian mantled gneiss domes⁵. Many of the Ordovician and Silurian psammitic strata along the anticlinorium are quartzose, and the early Silurian Clough quartzite that rests unconformably on the volcanics and gneiss domes is conglomeratic with very common pebbles of vein quartz within orthoquartzite matrix⁶. Although there is no easy solution to the provenance problem here or in the Trondheim region, most workers regard the rocks in the Bronson Hill anticlinorium as originating on an ensimatic arc complex within a closing Iapetus Ocean^{7,8}.

The calc-alkaline volcanics in western Norway possibly do represent an arc complex further west than the Trondheim arc. However, the presence of neither a western arc nor ophiolites in the Bergen area⁹ helps resolve the ambiguity of subduction polarity in the Trondheim region. Was there a western Iapetus seaway that closed into a second arc?

Corrigendum

In the letter '(ADP-ribose)_n participates in DNA excision repair' by B. W. Durkacz *et al.*, *Nature* **283**, 593–596, in Fig. 2 the symbols are incorrectly defined. It should read '△, 0 min; ▲, 40 min; ●, 80 min; and ○, 300 min'. Lines 16–17 of Fig. 2 legend should read 'a, b. The cells were exposed to DMS for 20 min, which was washed out, but 3 mM 3-aminobenzamide was added to the medium for the 300 min recovery period. c, d. The cells were exposed only to DMS'.

Errata

In the letter 'Plasmid-mediated tissue invasiveness in *Yersinia enterocolitica*' by D. L. Zink *et al.*, *Nature* **283**, 224–226, a line was omitted from paragraph 4. Line 4 should read '... Serotype 0:8 strains contained either a plasmid of molecular weight (MW) 35×10^6 , a plasmid of MW 41×10^6 or both (whereas...)'.

In the letter 'Do genealogical patterns in purple photosynthetic bacteria reflect interspecific gene transfer?' by C. R.

Woese *et al.*, *Nature* **283**, 212–214, the x axis in the upper part of Fig. 1 should be labelled S_{AB} and the x axis in the lower part should be labelled % Sequence homology.

In the letter 'The relationship between coding sequences and function in haemoglobin', by W. A. Eaton, *Nature* **284**, 183–185, on p. 184 second paragraph line 11 should read '...(2) Residues in the $\alpha_1\beta_2$ contact'.

Electrophoresis in the Separation of Biological Macromolecules

by O. Gaál, *Institute of Nutrition, Budapest*

G.A. Medgyesi, *National Institute of Haematology and Blood Transfusion, Budapest,*

and L. Vereczkey, *Chemical Works of Gedeon Richter, Budapest*

This book reviews the methodology of electromigration techniques. During the approximately forty years' history of modern electrophoresis, a large number of methodological variations have been created. The aim, therefore, has been to outline the principles and practice of the most important variants and to provide representative examples of their application for the study of proteins, nucleic acids, and glycosaminoglycans, but not to survey overall the literature of electrophoresis.

The Hydrophobic Effect: Formation of Micelles and Biological Membranes 2nd Ed.

by C. Tanford, *Duke University*

This edition gives a simple explanation for the formation and properties of biological membranes. It includes the theoretical treatment of micelle formation, making it possible to predict (from first principles) the size and size distribution of micelles formed by many simple amphiphiles, as well as the critical concentration at which they first form.

The Biochemistry of Inorganic Polyphosphates

by I.S. Kulaev, *Moscow State University, Institute of Biochemistry and Physiology of Microorganisms, USSR Academy of Sciences*

This book briefly describes the chemical properties of polyphosphates, but is concerned mainly with the metabolism of poly- and pyrophosphates in microorganisms. It is, in fact, the first book on the biochemistry of inorganic polyphosphates. One of the chapters deals with the possible role of polyphosphates in chemical and biological evolution.

Semisynthetic Proteins

by R.E. Offord, *Department of Zoology, University of Oxford*

In this monograph, the author has collected the previously scattered descriptions of the techniques of protein semi-synthesis into one place. A great many practical examples are included in the text, many of them drawn from procedures that originated in the author's own laboratory, or which were further developed there. Some of these were previously unpublished, and those that have been published before now include, where appropriate, the latest alterations to points of detail.

Antifungal Chemotherapy

edited by D.C.E. Speller, *Department of Bacteriology, University of Bristol*

The growing interest in the treatment of fungal infections reflects the commonness of superficial mycoses and the ubiquitous, if less frequent occurrence of deep mycoses in modern medical treatment. There is a small, but increasing range of effective drugs. The three sections of this book review the antifungal agents that have been administered systematically, discuss the treatment of superficial and deep fungal infections caused by 'opportunistic' and 'pathogenic' fungi, and describe the role of the laboratory, giving straightforward methods for the monitoring of antifungal treatment.

Oxford University Press

The Origins and Early Development of the Heavy Chemical Industry in France

John Graham Smith

Although France's prominent role in the history of the chemical industry has long been acknowledged, it has been relatively little studied. This first comprehensive book on the subject focuses on three central developments in the period 1770–1820; sulphuric acid manufacture, chlorine bleaching, and above all the early Leblanc soda industry – this last arguably constituting France's greatest contribution to the Industrial Revolution. Illustrated £36

Two-Phase Flow and Heat Transfer

D. Butterworth and G. F. Hewitt

This book covers gas/liquid two-phase flow, two-phase heat transfer, hydrodynamic instability, and condensation, and finishes with a discussion of loss-of-coolant accidents in nuclear reactions. This edition is a paperback reprint; the hardback edition is going out of print. Illustrated paper covers £12.50

The Theory of Linear Induction Machinery

Michel Poloujadoff

This book brings together a wide range of previously scattered work. While the author concentrates on the theory of the subject, he also describes testing apparatus and surveys the data obtained. The applications of linear induction motors range from advanced ground transport systems to instrument transducers. £15
Monographs in Electrical and Electronic Engineering

Metal-Semiconductor Contacts

E. H. Rhoderick

'An excellent introduction to the subject for final-year undergraduates studying it as a special topic or project, for those about to engage in research in the field, and for professional solid-state physicists and engineers who seek a comprehensive survey of the physical processes underlying devices using metal-semiconductor contacts.' *British Book News*. First published in 1978, and now reprinted in paper covers. £5.95
Monographs in Electrical and Electronic Engineering

Bearing Systems

Principles and Practice

Frederick T. Barwell

The interacting parts of machines, known as bearings, may be regarded as systems. They fall into two classes; conformal and counterformal, which are typified by plain bearings on the one hand and roller bearings on the other. The selection of the best type for use in any given product is a complex matter, and this book reviews recent work, enabling the designer to base his choice on sound scientific principles. £25

Stirling Engines

G. Walker

Stirling engines have a wide variety of uses, for example, as prime movers, cooling engines, heat pumps, and pressure generators. Because of their favourable noise and air pollution characteristics they are under intensive development for automotive use. This book describes and classifies the many systems in which Stirling engines are used. £32

BOOK REVIEWS

Impressive inhibitors

Michael Cannon

THIS book is published by Wiley-Interscience as a sequel to *Nucleoside Antibiotics* which appeared in 1970. It describes the application of naturally occurring nucleoside and nucleotide analogues as biological probes in cellular reactions. The compounds listed and considered inhibit between them an impressive range of events including cell wall synthesis, protein synthesis, DNA and RNA synthesis, purine and pyrimidine interconversions, and the activities of both cyclic-AMP-phosphodiesterase and adenosine deaminase. Several of the compounds are of medical importance since they have limited use in the treatment of cancer and viral infections in humans.

It is of no surprise to find an old friend — puromycin — featured in the text. Many biochemists have successfully experimented with this most useful antibiotic to study the mechanism of peptide bond formation on ribosomes, the release of incomplete nascent polypeptide chains and the properties of the ribosomal binding sites for transfer RNA. What may be surprising to some, however, is the fact that there are 69 other compounds described here of which 40 or so have been discovered since the 1970 volume was published. The number of additional events inhibited has increased dramatically in line with the number of new compounds identified. Medical implications are also clearly indicated. In 1970, for example, only 5-azacytidine, of the nucleoside antibiotics, had been used to treat cancer, showing good activity against certain leukaemias and limited activity on some solid tumours, although predictably the drug frequently produces unpleasant side effects. Of the newer compounds described in the present volume, both the pyrrolopyrimidine nucleoside antibiotic tubercidin and 9- β -D-arabinofuranosyladenine (ara-A), the latter having low myelosuppressive activity in humans, have been cleared by the Federal Drugs Administration for the treatment of human basal cell carcinoma, herpes

Nucleosides as Biological Probes. By R. J. Suhadolnik. Pp.364. (Wiley: New York and Chichester, UK, 1979.) \$50, £23.

simplex keratitis and herpes simplex encephalitis. Tubercidin is also a potent anthelmintic agent, as is the pyrimidine nucleoside disaccharide analogue hikizimycin (anthelmycin).

The presentation in this book is fairly standard for each entry and usually covers discovery, production, isolation, physical properties, chemical and biological properties, structural elucidation, biosynthesis, toxicity and where known the mode(s) of action. The 'interest generation' is extremely variable. Some compounds come over as fascinating and remarkable inhibitors. Thus coformycin and 2'-deoxycoformycin inhibit adenosine deaminase, an important enzyme in purine metabolism, a deficiency of which produces an inborn error of metabolism associated with severe combined immunodeficiency disease. The role of these two compounds as immunosuppressants aids the success of tumour grafts and indicates a usefulness in organ transplantation. Other compounds, by contrast, come over as being somewhat boring but it is fair to say that in each case beauty, or lack thereof, will always be in the eye of the beholder.

All but two of the ten chapters end with a particularly valuable summary section drawing together many of the important facts in concise form. Of the two chapters lacking a summary one deals exclusively, albeit briefly, with clitidine and tells us very little of the biological properties of this pyrimidine nucleoside, although we do discover that it resides in the mushroom *Clitocybe acromelalga* and is a physiologically active substance. One presumes that little is, in fact, known about this compound. The remaining summary-less chapter deals equally briefly with the herbicides A and B, 5'-O-glycosyl-ribonucleosides, raphanatin and 6-benzylamino-7- β -D-glucopyranosylpurine. Curiously we are told that the herbicides

show promise as weed killers but are not toxic to mice (or gardeners?).

The text is profusely illustrated not only with the chemical structures of the various compounds described but also with a large selection of diagrams and tables reproduced from original papers. I can understand the author's wish to underscore his factual writing with real experimental data but I found this aspect of the book very annoying on occasion. Certainly these entries fill out the volume but much of the original experimental data presented are, in my opinion, redundant. For example, I am prepared to accept the author's word that cordycepin (3'-deoxyadenosine) inhibits the synthesis of ribosomal RNA and if I found this observation of particular interest I should naturally read the relevant reference. I see little reason why the present text should labour the point by illustrating an experiment involving agarose gel electrophoresis of ribosomal RNA from L1210 cells treated with the inhibitor. Again, an illustration is hardly necessary to support the statement that whereas RNA polymerases isolated from either *Escherichia coli* or T3 bacteriophage are not affected by α -amanitin, the former enzyme is completely inhibited by the naturally occurring nucleotide analogue thuringiensin whereas the latter enzyme is not. There are many other such examples throughout the text.

Overall, however, this will be a useful volume for those who are interested in the subject area — although whether or not the number of such individuals represents a viable economic proposition for Wiley-Interscience, and hence for Professor Suhadolnik, is debatable. Certainly, though, the text makes the reader aware of the remarkable versatility of nucleoside and nucleotide analogues with respect to their inhibitory effects and allows for interesting speculation in the fascinating field of structure-function relationships.

Michael Cannon is Lecturer in Biochemistry at King's College, London, UK.

Mammalian vestibular physiology

R.H.S. Carpenter

Mammalian Vestibular Physiology. By V. J. Wilson and G. Melvill Jones. (Plenum: New York and London, 1979.) £20.48.

WHY do neurophysiologists choose to study one part of the brain rather than another? Amongst sensory systems, at least, it seems to be those which give us the greatest sensual enjoyment that attract the closest investigation: if we add to this the inevitable band-waggon effect, the result is a strikingly disproportionate amount of effort on vision and to some extent hearing, and rather little on anything else. The vestibular system has fared particularly badly from this: apart from the ambiguous delights of the roller-coaster and sky-diver, the system comes to most people's notice only at times of distinct misery — a bad Channel crossing, the acute effects of alcoholic overindulgence — and its contribution to the unending task of keeping us precariously balanced on two tiny supports goes largely unnoticed and unappreciated.

Of course, it has to be admitted that the vestibular system is somewhat redundant, in the sense that much of the information about head position and movement that it provides is also furnished (though more slowly) by the visual system and by proprioceptors in our joints. A man whose vestibular system has been destroyed by disease may not be aware that much is wrong until these alternative sources of information are also unusable — running over rough ground in the dark, or swimming underwater. But as Wilson and Melvill Jones make abundantly clear, these parallel visual and proprioceptive inputs seem largely to make use of the neural circuitry that was originally evolved to process vestibular information; and the study of central vestibular pathways has shed a good deal of light on how information from the eyes and other receptors is used for the same purpose.

One aspect of this cooperation that is particularly interesting, the importance of which has only recently been fully appreciated, is the way in which the matching of visual and vestibular signals is a function that must be *learned* by the brain: this calibration of one input in terms of the other seems to be going on all the time, ensuring that degenerative and other changes in the performance of the vestibular organs do not result in inappropriate responses. A dramatic way of demonstrating this is to get a subject to wear prisms that reverse his visual field: after only a matter of days it is

found that certain of his purely vestibular responses — ones that can be evoked in the dark — follow suit by reversing their direction as well. These changes are almost certainly the result of functional alterations in cerebellar circuitry, and offer the exciting possibility of studying motor learning by the cerebellum in a simple and quantifiable way.

Mammalian Vestibular Physiology provides a first-class account not only of these more recent areas of interest but also of the classical anatomy and physiology of the vestibular organs and their central connections, and fills much more than adequately what has long been an obvious gap in the literature. It is sufficiently wide

in its scope to be of interest to neurophysiologists in other areas as well as to specialists in vestibular and oculomotor physiology, who will certainly find both its intelligent and impartial reviews of difficult topics, and its notably comprehensive bibliography, of more than ephemeral value. Perhaps it may also help to lure neurophysiologists away from the rather obvious charms of visual physiology to a field which promises to begin to unveil the more challenging mysteries of the motor system. □

R. H. S. Carpenter is Lecturer in Physiology at the University of Cambridge, UK.

Laser fusion

Siegbert Witkowski

The Physics of Laser Fusion. By H. Motz. Pp.290. (Academic: London and New York, 1979.) £17; \$37.

IT is a rather bold undertaking to write a textbook on the physics of laser fusion, for essentially two reasons. Firstly, laser fusion is a very rapidly developing field. The interpretation of the complex phenomena has only reached a quasi-steady state which has not yet been proven to be stable against new experimental results. Secondly, the physics of laser fusion comprises a large variety of quite different topics. Therefore, selection of the proper material for an introduction to this field is a major problem. The author has succeeded in this difficult task. He has chosen the essentials, concentrating on the basic phenomena, which are well established. The physics of the nuclear reactions and of high power laser systems

are only touched on briefly in the introductory chapters in order to acquaint the reader with the problems involved and the state of the art. The main part of the book deals with light plasma interaction processes, the excitation, propagation and interaction of waves in plasmas and their relevance to laser fusion. The complex phenomena connected with energy transport in the overdense region are touched on in a special chapter preceding the treatment of the hydrodynamics and its stability. Besides the analytical treatment of the phenomena, results from computer codes are also presented. Each chapter is followed by a list of references where more detailed information can be found on specific subjects. In conclusion, this book can be recommended as an introduction to the field of laser fusion for newcomers, but it is also a useful compilation of the basic physics of laser fusion for the specialist. □

Siegbert Witkowski is a member of the Board of Directors, Projektgruppe für Laserforschung, Munich, FRG.

Models of *r* and *d*

Alan Grafen

The Natural Selection of Populations and Communities. By D.S. Wilson. Pp.186. (Benjamin Cummings: Menlo Park, California, 1980.) \$12.95.

IN whose interest does an animal or plant behave? Evolutionary theorists believe that the workings of natural selection ensure that organisms act as if they were maximizing their reproduction (or more precisely, a weighted sum of their own and their relatives' reproduction). So although some kinds of behaviour might easily be explained as an individual acting in the interests of some larger unit such as its

group, species or community, the orthodox view is still that only in extreme and implausible conditions can this type of explanation be admitted. In *The Natural Selection of Populations and Communities*, D.S. Wilson attempts to give a theoretical justification for accepting these 'higher' levels of selection.

This book contains much to commend it to biologists interested in natural selection. Wilson's discussions, in the introduction and elsewhere, of the logic of his attempt are excellent. The idea of "trait groups" as the population subdivision within which frequency dependence operates,

PRINCIPLES OF BIOLOGICAL AUTONOMY

by **Francisco J. Varela**, *University of Chile, Santiago and The Brain Research Laboratories at New York University Medical Center*

The North Holland Series in General Systems Research.
Vol. 2. Dr. George Klir, Editor

The continuous interplay of autonomy and control span a very broad range — from genetics to psychotherapy. In this book the basic characteristics of autonomy, the processes of cellular self-construction, are examined in a detailed analysis and lead to a generalization of recursive processes present throughout natural systems. Dr. Varela provides an explicit definition of what autonomy and autonomous systems are, describes formal tools to represent them, and applies this mode of analysis to the immune and nervous systems, and their cognitive processes. This foundation work incorporates a number of results from many disciplines into a new approach to biological and cognitive mechanisms.

Cold Spring Harbor Symposia On Quantitative Biology Volume XLIV: Viral Oncogenes

The 141 papers in this volume cover all aspects of the molecular biology of tumor viruses, both DNA and RNA. However, the value of the volume is considerably greater than the sum of the individual contributions. The reader is able easily to compare the properties of the various virus-coded proteins responsible for transformation; to learn what

is known of the mechanisms by which the synthesis of these proteins is controlled; and finally to begin to understand how these proteins interact with cellular structures to produce the transformed phenotype.

CONTENTS

Part 1

Introduction:
Viral oncogenes (Temin)

Synopses

Transforming genes of DNA tumor viruses (Crawford); Transforming genes of retroviruses (Duesberg)

DNA Tumor Viruses: Early RNAs and Early Proteins

Transcription in SV40-transformed cells (Ghosh); SV40 RNA splicing (Khoury); Third splice site in SV40 early mRNA (Mark); Polyoma virus transcription in transformed cells (Kamen); SV40 transformed cell transcription (Grigoryan); Viral RNA synthesis in transformed cells (Flint); T antigen ATPase (Tjian); Enzymatic activities of T antigen (Griffin); SV40 T antigen biochemical properties (Prives); Polyoma virus T antigens (Hunter); Polyoma virus middle T antigen (Smith)

T Antigens

Polyoma T antigens in transformed cells (Ito); SV40 F-gene protein (Tegtmeyer); Phosphorylation of SV40 large T antigen (Walter); T antigens of SV40-transformed cells (McCormick); SV40 large-T-host-53K-protein complex (Crawford); New genetic information expressed in SV40-transformed cells (May); T-antigen-associated nuclear proteins (Melero); SV40 17K-protein-cell-protein complex (Rundell); Cellular SV40 T antigen (Linzer); SV40 T-antigen-related cell-surface proteins (Deppert); SV40 transplantation antigen (Tevethia); Stimulation of host antigen by SV40 small-T function (Kasamatsu); EBV-induced transformation (Klein)

The Genetics of Transformation by DNA Tumor Viruses

Hr-t gene of polyoma virus (Benjamin); Transformation properties of polyoma virus mutants (Griffin); SV40 deletion mutants (Pipas); Origin-defective mutants of SV40 (Gluzman); New polyoma virus mutants (Vasseur); SV40 temperature-sensitive deletion mutant (Pintel); Transformation by SV40 (Martin); Transformation with wild-type and mutant SV40 (Frisque); Cell transformation by polyoma virus and SV40 (Rassoulzadegan); SV40 A gene and transformation (Hiscott); Additional early sequences of adenovirus (Williams); Ad5 host-range mutants (Shenk); SV40-induced mutations and transformation (Theille)

The Transforming Genes of Adenoviruses and Their Expression

Viral transformation genes (van der Eb); Ad2 early and intermediate RNA (Chow); Ad2 promoters (Baker); Ad5 hr mutants (Berk); Expression of adenovirus region 1 (Spector); Metabolism of Ad2 mRNAs (Wilson); Adenoviral

early and transformation proteins (Green); Cloned adenoviral mRNAs (Perricaudet); Transforming proteins of Ad5 (Lassam); Ad5-associated protein kinase activity (Branton); Mapping of adenoviral early proteins (Lewis); E3-19K glycoprotein and transplantation antigens (Persson); Ad12 transforming gene (Fujinaga); Ad12 transforming-gene products (Shiroki)

Transforming Genes of DNA Tumor Viruses and Their Arrangement in Transformed Cells

Adenovirus-transformed cells (Visser); Sites of adenoviral DNA integration (Doerfler); Methylation of integrated adenoviral DNA (Sutter); Integration of SV40 and adenoviral DNAs (Sambrook); Mechanism for circularization of MVM DNA (Aloni); Tumorigenicity of polyoma virus in hamsters (Israel); Polyoma virus DNA sequences in transformed cells (Lania); Monkey cells transformed by SV40 DNA fragments (Graessman); Polyoma virus excision (Basilico); Isolation of host-substituted SV40 variants (Winocour); Transforming fragments of HSV DNA (Reyes)

The Transformed Cell

SGF binding and elution from EGF membrane receptors (DeLarco); Transformation-specific secreted proteins (Senger); Transformation-related protein p53 (Jay); Regulation of PA synthesis (Rifkin); PA activity of transformed cells (Mangel); Tumorigenic syndrome in vitro (Pollack); Expression of transformation in cell hybrids (Jha); Tumor formation in nude mice (Kahn); Tumorigenicity of adenovirus-transformed cells (Gallimore); Transformation-related antigens (VedBrat)

Part 2

The Genomes and Proteins of Retroviruses

Murine sarcoma virus genomes (Donoghue); MuSV transforming genes (Canaani); Cloning integrated MSV provirus (Vande Woude); Proteins of ts transformation mutant of MuSV (Wood); Cellular and viral transforming sequences (Wang); Transforming protein of rASV (Karess); Cell killing by avian retroviruses (Temin); Endogenous rat leukemia and sarcoma viruses (Rasheed); Molecular species carrying FOCMA (Snyder); Genetic structure of leukemia viruses (Bister); RNAs of Friend polycythemia and anemia virus (Evans); RNA of R strain erythroblastosis virus (Toyoshima); Stable src gene of LA23 RSV (Darlix); Ab-MuLV genome (Baltimore); Ab-MuLV kinase (Witte); Ab-MuLV isolates differing in p120 (Rosenberg); Mammalian RNA type-C transforming virus-coded proteins (Stephenson); SFFV-specific RNA and proteins (Ikawa); Shutdown

of viral gene expression (Berkower); Genetic control of SFFV-specific sequences in normal mice (Mak); Synthesis of MSV-specific polypeptides in vitro (Dina)

src

Protein phosphorylation by pp60^{src} (Erikson); Avian retrovirus transforming genes (Bishop); Structure and function of ASV pp60^{src} (Hunter); RSV transforming proteins (Kamine); Activities of the src-gene product (Maness); Protein kinase activities in normal and RSV-transformed cells (Owada); F-actin and src-gene product (Tsen); Polypeptide phosphorylation in transformed cells (Radke); Viral oncogenes and neuroretinal cells (Calothy); Localization of the src-gene product (Goldberg); Reactivation of RSV temperature-sensitive mutants (Friis); Localization of pp60^{src} (Rohrschneider); Nature and location of RSV src-gene product (Pastan); RSV transformation (Anderson); Glucose transport (Lipmann); src-independent focus formation (Breitman); pp60^{src} in ASV-transformed and reverted mammalian cells (Lau); Reversion of ASV-transformed rat cells (Wyke)

Provirus and Their Expression

Endogenous and exogenous proviruses (Hughs); Avian sarcoma virus DNA (Taylor); Avian endogenous proviral DNA (Skalka); Endogenous viral loci in the chicken (Astrin); Endogenous viral expression (Hayward); c region regulation of ALV growth rate (Tschlis); Subgroup-E ALV-associated disease (Robinson); Murine leukemia virus DNA (Lowy); Molecular clones of MMTV (Donehower); Genomic location of MMTV proviral DNA (Hynes); Transformation by avian retrovirus DNAs (Cooper)

The Transformed Phenotype and Differentiation

Murine hematopoietic cell lines (Teich); Differentiation of cells transformed by Friend virus (Housman); Transformation by Ab-MuLV (Raschke); Cell-surface antigens of Ab-MuLV and F-MuLV (Risser); B-cell activation and retrovirus expression (Moroni); In vitro transformation by SFFV (Hankins); Viral oncogenes in avian acute leukemias (Stehelin); Defective leukemia viruses (Graf); Avian oncovirus recombination (Eisenman); Differentiation precedes transformation (Boettiger)

Viruses of Thymic Leukemia

Characterization of AKR MuLV (O'Donnell); Association of MCF viruses with leukemogenesis (Rowe); A progress report: Genomes of MCF viruses (LiLung); Nucleotide sequence of M-MuLV (Sutcliffe); MuLV env-gene expression (Famulari); Generation of oncogenic mouse type-C viruses (Rapp); Retroviral-receptor-mediated leukemogenesis (McGrath)

This book brings together for the first time a variety of animal models in cancer research, from the simple immunodeficient foetus to the complex genetic manipulation needed to produce the 'Lasat' mouse deficient in both thymus and spleen.

This is the first book to deal with this aspect of cancer research in such detail and it will be valuable reading for all those involved in cancer and immunological research. It will also be an important reference for students undertaking courses in Cancer Studies or Immunology.

contrasted with the "deme" within which there is free interbreeding, had seemed a contrivance, but the book convinced me of its biological interest. His concept of the "neutral pathway" is very stimulating. The examples are fascinating and show that the debate is about animals and not algebra, and the burying beetles in particular provide a challenge to ordinary, individual selection thinking.

A very valuable aspect of a book in which every main point is made with a model is that disagreements about it can be precisely stated. Wilson makes two controversial claims about his structured deme model which I believe to be mistaken. The first is that it "routinely" allows the evolution of a kind of altruism not predicted by the orthodox, individual selection model. The second is that species should act more in the interests of the community than the individual selection model predicts, because of "indirect effects". This second claim underlies the whole second half of the book. I believe that in making these important claims, Wilson has been misled by subtleties in his own algebraic formulations. The models supporting the two claims are very similar, and the following argument about "weak altruism" can be easily applied to "indirect effects".

To explain this rather important error, I will describe briefly the conclusions of the algebraic model. The effect of a trait is that its possessor has d more offspring while

every other member of the trait group has on average r more offspring. (Often either d or r will be negative.) Wilson first shows that in the individual selection model the trait will spread if $d > r$. This is because the trait group is the deme and a possessor of the trait must do better than average in the deme.

The condition for spread in the structured deme model depends on how the deme is divided into trait groups. If each group has exactly the same proportion of possessors of the trait — the identical groups case — then it is $d > r$. If possessors and nonpossessors of the trait are divided randomly into groups then it is $d > 0$. Wilson points out that there is a class of traits with $r > d > 0$ which will spread with random grouping but not with identical grouping, and these he calls "weakly altruistic". So far so good.

He goes on to identify the individual selection model with the identical grouping case of his structured deme model, and I believe this is an error. He concludes that the individual selection model is very special and implausible, and that we should expect to see animals behaving more generously towards each other than the individual selection model predicts. This is an important claim.

In both the individual selection model and the identical groups case the condition for spread is $d > r$, so how can Wilson be mistaken in identifying them? Because r must be interpreted differently in the two

cases. In the individual selection model every other member of the *deme* gains r but in the identical groups case only the other members of the *trait group* do. To see the significance of this difference, consider how the random groups case should be understood in terms of the individual selection model. The trait benefits each other member of the group by r , but it is the average effect on other members of the *deme* we need to use in the individual selection model. Wilson assumes that there are many groups in the deme, and so when the group members' r values are averaged over the whole deme the result will be very small. The condition for spread in the individual selection model then becomes nearly $d > 0$, even though r may be reasonably large. (In fact, the condition in the random groups case itself is only "nearly" $d > 0$.)

The random groups case, therefore, corresponds to the orthodox, individual selection model, and "weak altruism" is not, after all, a major contribution of structured deme theory to evolutionary thought. And, by a similar argument, neither is the concept of "indirect effects".

In conclusion, this book contains a very stimulating and clearly presented argument for using 'higher' levels of selection; but an argument which is seriously flawed. □

Human internal clocks

J.T. Enright

The Circadian System of Man. By R.A. Wever. Pp.276. (Springer: Berlin, Heidelberg and New York, 1979.) DM98; \$53.90.

THIS monograph summarizes the results from some twelve years of experimental studies on human circadian rhythms, conducted in a unique underground facility at the laboratories of Professor Jürgen Aschoff in Bavaria. Data are available from more than 200 experiments, with an average duration of about a month each, during which the subjects — usually singly but sometimes in groups of 2 to 4 — lived in complete temporal isolation from the outside world. A few dozen comparable experiments have been conducted by others, elsewhere, but Wever's data base is such that this treatise can be taken as a definitive statement of present knowledge on the topic. Many of these results, which involve both free-running and entrained rhythms, have been previously published as a series of technical reports; nevertheless, there are conspicuous

advantages to having everything available in the present compact form: a well organized and systematic consideration of all the data, rather than interim, single-topic progress reports.

For me, the most interesting issue involved in these studies is the comparison of human circadian rhythms with those of other well studied vertebrates. Probably the most conspicuous difference is the extreme lability sometimes seen in the wake-sleep patterns of human subjects, superimposed on a more stable background of regular cycles in body temperature and other 'vegetative' rhythms. One hamster or mouse or finch seldom differs from the next by more than an hour in the free-running period of its wake-sleep rhythm, but some 20% of the human subjects had grossly non-circadian wake-sleep patterns (periods as short as 16 hours and as long as 60 hours). Subjects who thought they were living a normal routine occasionally undertook 'sleep deprivation' without even being aware of it: sustained wakefulness of up to 48 hours, while the temperature rhythm went on with its 24- to 25-hour oscillation. Another of the interesting differences between humans and other vertebrates, probably reflecting our domestication, is that lighting regimes — the overwhelmingly strongest synchron-

izing agents for the circadian rhythms of other animals — apparently are only subsidiary in humans to the stronger effects of various sorts of social synchronization.

Wever himself has supervised all the massive programme of research described here, and the interpretations of the data are, of course, his own. Some of those interpretations are inevitably less convincing than others, and each reader will no doubt find certain issues about which he has reservations. It strikes me, for example, as over-interpretation, when the phase relationship between the body-temperature rhythm and the wake-sleep cycle is taken not just as a hint, but as proof that a subject's rhythm was accidentally synchronized by some unintended environmental cycle (p.38). I also wonder what to think about the implications of electromagnetic fields for the rhythms: small differences in mean period, correlated with shielding from natural electromagnetic fields, were statistically significant during the first 5 years of experimentation ($n=84$); but I find it distressing

to see that the effect was not reproduced during the subsequent 8 years of studies (p.96; $n=58$). An imposed 10-Hz square-wave electric field was associated with a shorter circadian period for 12 of 17 subjects tested (the other 5 excluded because of "internal desynchronization"); but in subsequent experiments, a 10-Hz sinusoidal field led to equivocal results (p.114). This difference can in principle be attributed to higher harmonics in the square-wave signal — or does it instead reflect on the reproducibility of the initial finding?

But these and similar questions are minor matters. Regardless of details in the interpretation, this monograph offers a wealth of data; it is an irreplaceable source book for those interested in the experimental study of human circadian clocks. □

Igneous petrology fifty years on

R. N. Thompson

The Evolution of the Igneous Rocks. Fiftieth Anniversary Perspectives. Edited by H.S. Yoder Jr. Pp.588. (Princeton University Press: Guildford, UK, 1979.) Hardback £19.30; paperback £8.40.

IN 1928 N. L. Bowen wrote his masterpiece *The Evolution of the Igneous Rocks*. This book caused a revolution in the philosophy and approach of igneous petrology by demonstrating that many aspects of the behaviour of magmas could be explained adequately by straightforward application of chemical principles, without the addition of the pinch or two of geological magic dust so frequently used by other theoreticians of Bowen's time. The 18 eminent petrologists who have contributed to the fiftieth anniversary volume are all the inheritors of Bowen's approach to magma chemistry. Each was asked to take a chapter of the original book and describe what has happened in that part of the subject during the following half century. As might be expected, there are great differences in the ways in which the various authors have approached their task. Some of them alternate extensive quotations from Bowen, or paraphrases of his ideas, with balanced summaries of the present state of knowledge on each theme. In contrast, a few of the contributors have been unable to resist the temptation to use their chapters almost solely as vehicles for summarizing their own work and reiterating their own views; in one article

there is no mention at all of either Bowen or his book.

Taken as a whole, the many excellent articles far outweigh the few others. The chapters that I found particularly interesting were on silicate liquid immiscibility (Roedder), crystal accumulation and sorting (Irving), siliceous potassic glassy rocks (Stewart), volatile constituents (Burnham) and petrogenesis (Wyllie). There are also many sections of valuable data and discussions in other chapters and I anticipate that this book is one which almost every working igneous petrologist or geochemist will wish to buy. On the other hand, it is probably of only limited use to the wider readership of students. The reason for this lies in the terms of reference of the volume. Rigorous adherence by the contributors to the themes in igneous petrology which Bowen chose in 1928 has inevitably led to omission, or virtual omission, from the 1979 book of any subjects which were neglected or completely unrecognized 50 years ago. This policy leads to a curious overall impression in the book, because many aspects of current igneous petrology are discussed in detail, whilst other important themes, such as crystallization kinetics, and trace-element and isotope geochemistry, are almost completely omitted. The irony is that, if Bowen had rewritten his own book in 1979, these are exactly the sorts of forward-looking applications of chemical principles to igneous petrology that he would have emphasized. □

R. N. Thompson is Lecturer in Geology at the Imperial College of Science and Technology, University of London, UK.

Selective electrodes

J.A.W. Dalziel

Working with Ion-Selective Electrodes. By K. Cammann. Pp.225. (Springer: Berlin, Heidelberg and New York, 1979.) DM 76, \$41.80.

THIS monograph, a worthy successor to others that have appeared, is a translation from a second German edition. It reviews 447 publications up to 1977. The author, after experience in the applications department of an instrument manufacturer, claims an understanding of the problems that face the users of ion-selective electrodes. He considers that their difficulties arise mainly from lack of knowledge and remedies this in two ways — first, with a theoretical treatment to serve as reference in understanding the action of electrodes in potentiometry generally, and then by offering practical advice on their construction, mode of operation and a survey of their present range of applications.

Particular emphasis is given to consideration of pitfalls in the reproducible measurement of electrode potentials, with advice on reference electrodes, buffers and liquid junction potentials directed towards stable e.m.f. measurements of high impedance cells. The different categories of ion-selective electrodes (solid-state glass, homogeneous and heterogeneous membranes, supported ion exchanger and neutral carrier membranes, and electroactive coatings, gas-diffusion and bio sensors, but without the glass pH electrode which is intentionally omitted) are all described in turn with full practical details, including methods of construction.

The second half of the book has sections on techniques and applications. Besides calibration and the direct measurement of activity (concentration) under static conditions, much space is devoted to titration procedures with indicator electrodes, using the Gran extrapolation and other methods which allow for the slow response of some electrodes near the end point. Whether such methods would be chosen for routine situations is questionable. The short section on continuous measurements in industry and environmental research should be more interesting, but in fact the progress reported is rather disappointing when one remembers that it is over 15 years since 'new' ion-selective electrodes were made. For the future, the important step will be to discover better ways of interfacing the electrolytic species in sample solutions so that they react directly and selectively with electronic charge carriers within semiconducting electrodes. □

INSERM CONFERENCES INSERM CONFERENCES INSERM CONFERENCES INSERM CONFERENCES INSERM CONFERENCES

The French Institute of Health and Medical Research (Institut National de la Santé et de la Recherche Médicale) is organizing a series of meetings on advanced research topics in various biomedical fields. The meetings which started three years ago, are known as the INSERM CONFERENCES.

The aims of the conferences are :

- to foster the exchange of ideas, to evaluate new methods and new lines of investigation ;
 - to bring together scientists, mostly from European countries, working in universities and public or private research institutions.
- The meetings will be held under the direct responsibility of a chairman and a co-chairman.

The INSERM CONFERENCES have the following special features :

- only highly topical subjects are dealt with ;
- if possible, the data presented should not have been the subject of any earlier complete publication, a condition which therefore excludes general reviews ;
- the Conferences do not publish proceedings or any other material, even in a summarized form.

The chairman of each INSERM Conference will invite 15 to 20 scientists to give a report in line with the above conditions. The number of contributions will be limited to three of four per session and, at the discretion of the chairman, at least one third of the time will be given over to discussion and brief informal communications.

In addition to the invited speakers, at least fifty participants will attend the meeting, and efforts will be made to select young scientists. Experienced research workers from fields other than those relating to the Conference will also be welcome to attend. Participants will be chosen in such a way as to enable those engaged in all types of scientific research to establish personal contacts, exchange information and find new ways of working together.

PRACTICAL ARRANGEMENTS

The INSERM CONFERENCES 1980 will be held at the Domaine de Seillac, near Blois (180 km from Paris), during the month of September (full address : Domaine de Seillac, 41150 Seillac, France). Each conference will last three and a half days, from Sunday evening (departure from Paris) to Thursday afternoon. Working sessions will be held from 9 a.m. to 12.30 p.m. and from 5.30 p.m. to 8 p.m. On free afternoons, participants will have a wide choice of leisure activities at the Domaine de Seillac and in the surrounding area (Tennis, Table-tennis, bicycling, visit to the Castles of the Loire).

REGISTRATION FEE

Participants whose applications are accepted but who are not invited speakers, will be asked to pay their registration fee and board (1200 FF).

Scientists wishing to attend this conference have to submit this application form BEFORE JUNE 6th to INSERM Conferences, 101, rue de Tolbiac - 75654 PARIS CEDEX 13, France - Telephone : 584-14-41 - extension 397.

10 April 1980

Eleventh hour for biotechnology in Britain

WHETHER or not the National Enterprise Board decides to, or is allowed to, set up a biotechnology company, the Spinks report published last week was right to have suggested that the Board consider the possibility (see page 502). There is little doubt that Britain has long been in need of companies prepared to risk investment in biotechnology. The only question now is whether it is too late.

As far back as 1975 it was obvious to a certain number of UK scientists that there was considerable commercial potential in new techniques emerging from molecular and cellular biology. In particular it was recognized that the technique of recombinant DNA might be used to harness bacterial and other cells to the production of pharmaceutically active polypeptides. Gene manipulation was also seen to have much to offer in the improvement of strains of microorganisms employed in fermentation and waste disposal. Bacterially cloned genes could also be foreseen as valuable in the diagnosis and therapy of congenital diseases. Equally there was early, if limited, recognition of the commercial potential of hybridoma cells which produce single antibodies — which are of considerable value in radioimmunoassays and other medical diagnostic techniques.

It was with some chagrin that scientists in Britain, including those responsible for some of the key discoveries, watched entrepreneurs in the US start up a series of small venture capital businesses aimed to cash in on the new techniques, whereas nothing equivalent emerged in the UK. It still has not.

Nor, with a few exceptions, have established UK industries been quick off the mark to exploit the new techniques. Most companies have seemed content to bide their time rather than to fund research that may have looked promising but whose value would not be proven without long term investment. In the event, progress abroad has been much faster than was anticipated. Although real fortunes, as opposed to paper ones, are not yet being made from the new biotechnology, there can be no doubt that they will be. And yet there is still a distinct lack of interest from UK industry.

With neither established nor new companies to fund and benefit from UK scientific expertise, universities and organisations such as the Medical Research Council and the Agricultural Research Council find it difficult to exploit commercially the discoveries of their scientists. Could their requirements be met by a publically financed company?

Any such proposal will meet three hurdles. The first is time; is it too late to set up such a company? Here the answer must be a qualified no. It is probably too late to think in terms of producing hormones and vaccines by means of genetically-manipulated bacteria; those are first generation applications already far advanced. But there is no shortage of second generation applica-

tions, particularly those involving fungal, mammalian and plant cells, with which a newly formed company might hope to leapfrog the early starters.

The second hurdle is manpower. While British industry and entrepreneurs have been dallying, many of the academic scientists have become involved with US-based, or US-financed, venture capital companies. Other British scientists have resisted all approaches and will probably continue to do so. It is therefore dangerously late to be recruiting scientists to the cause. Nevertheless there does appear to remain sufficient untapped expertise, particularly in the laboratories of those research councils most keen to see a company founded, to make the project worth pursuing.

The third hurdle is the Conservative government which, particularly with its present leaders, strongly favours private over public enterprise. But faced with a demand unfulfilled by the private sector no government should stand endlessly on principle.

If all three hurdles can be jumped, there remains the question of how best to set up a public company. The obvious way, as recommended in the Spinks report, is through the National Enterprise Board (NEB) and/or the National Research Development Corporation (NRDC). Although the NRDC already has some expertise and experience in the patenting and licencing of biotechnological processes, there are drawbacks to its further involvement. In the first place whereas it commonly gives a half share of royalties to any university from which a patented discovery has emerged, it is constitutionally unable to pass royalties back to research council laboratories. Secondly it is willing only to fund research with a clear commercial potential. Thirdly, and despite its having taken out such important patents as those on cephalosporins and interferon (unfortunately time-expired except in the US, where it runs until 1989), the NRDC has not consistently spotted the winners. One glaring mistake is its 1975 decision that hybridomas had no obvious commercial applications.

Given the drawbacks of the NRDC, there is a good case for the NEB to found a biotechnology company. The chief attraction of this proposal is simply that a new company, devoted to a relatively narrow venture, would be able to avoid most of the problems associated with the NRDC. Clearly the success of such a company would hinge crucially on the calibre of its staff, their ability to pick areas in which they could mount an effective challenge to those companies already in the business, and the degree to which productive links could be built and maintained with academic scientists.

None of this will be easy. It will become even less easy as time passes. Therefore if, as we believe, the NEB should start a biotechnology company in the UK it should do so now. □

United States

Budget cuts stop research growth

Delays in space science missions, construction of a heavy ion accelerator, and a scheme to improve university research facilities are among the victims of last week's US budget cuts. **David Dickson** reports

It could have been worse — and for a time it looked as if it was going to be. But when President Carter announced last week where the axe was to fall in his attempt to balance the federal budget, it became clear that the growth enjoyed by basic research for the past few years has, at least temporarily come to a halt. Indeed the first indications are that the cuts, reducing expansion to below the expected inflation level, will mean a net contraction in overall funding.

Hardest hit will be the National Science Foundation, which had expected a 17.7% growth in its budget in 1981, but has had this reduced by \$74 million to an 11% increase. Close behind is the National Aeronautics and Space Administration, although the space shuttle programme has been protected from cuts, largely because of its commercial and military significance.

In other agencies the impacts have been less severe. The Department of Energy, for example, has had the growth in its basic research budget cut from 13.4% to 12.2%. And at the National Institutes of Health, where possible cuts of up to \$500 million had initially been discussed (largely because it is one of the few areas of discretionary spending in the health budget), it was finally agreed to reduce the 1981 basic research budget by only \$35 million out of \$1,704 million.

Dr Frank Press, Director of the Office of Science and Technology Policy, told *Nature* last week that in deciding where the President's original budget proposals for 1981 should be reduced, it was decided to aim primarily for demonstration and development projects rather than basic research support.

"New initiatives were slowed down but not dropped if they were philosophically important to us" said Dr Press.

Some of the more detailed cuts are: ●NASA: total research and development budget reduced from \$5.7 to \$5.5 billion. The space science budget, previously planned to rise from \$600.9 million to \$668 million, will now fall to \$561 million.

In addition to a two-year delay in the Solar Polar Mission, future experiments in physics, astronomy, life sciences and environmental observation planned for flight on Spacelab missions will be delayed for one to two years.

These cuts will leave unaffected two new starts proposed for the 1981 budget, namely the Gamma Ray Observatory, and the National Oceanic Satellite System. Nor

will the cuts effect either the Galileo Mission or the space telescope, both initially under threat when possible cuts of up to \$760 million were being discussed.

However funding for the Earth Radiation Experiment, NASA's proposed contribution to the National Climate Plan, will be delayed for one year. And the agency will also be cutting back on cosmic ray research, as well as terminating relativity research and the analysis of data from earlier pioneer missions (although the latter will be kept for future analysis).

●Department of Energy: the high energy physics programme will be cut by \$4

million from its original proposed level of \$359 million. This cut will be absorbed at Brookhaven, where the construction of Isabelle is already experiencing delay due to problems with the superconducting magnets.

A similar sum is being cut from the nuclear physics budget by deferring for one year construction of the Heavy Ion Beam Argonne tandem accelerator system.

In addition, \$3million inserted into the budget to support the setting up of advanced energy research centres at leading US universities (an idea proposed only last autumn by Dr David Saxon, of the University of California) has been dropped.

●National Science Foundation: within the NSF two strategies have been pursued. Firstly to preserve as much as possible of core responsibilities for basic research.

Delay for space mission with Europe

Halley's comet: delays to the solar polar mission mean hope for a cometary mission for Europe

AMONG the organizations to be affected by the US budget cuts is the European Space Agency, which is collaborating with NASA on a project to send two spacecraft in complementary polar orbits around the Sun, known as the International Solar Polar Mission.

The Carter administration, which included the mission as a new start in last year's budget submission to Congress, is now proposing to save \$43 million in 1981 (compared to \$83 million proposed in January) by delaying the launch of the mission from 1983 to 1985.

The delay will cause serious programming problems for ESA, whose space science projects are already on a tight schedule, and which last summer signed a \$56 million contract with Dornier to construct the European spacecraft by 1983.

The agency now has to decide whether to allow construction to be completed as planned, and subsequently put the spacecraft in mothballs; or to slow down construction work, hoping that the money

saved can be absorbed by other projects and will not have to be returned at the end of the year.

Either strategy will make the project more expensive than when it was approved.

This particular cloud may, however, prove to have a silver lining. For some of the money freed from the ISPM might be available to support a fly-by mission to the comet Halley, which would have to be launched at the end of 1984.

After NASA had informed ESA in December that it was unlikely to be able to support a joint mission to Halley and the comet Tempel 2 because funding for a solar electric propulsion system had been deleted by the Office of Management and Budget, ESA's scientific programme committee agreed last month that it would be prepared to consider a European solo mission, providing the costs are under 80 million accounting units (about \$110 million).

Detailed proposals for such a mission will be considered when the committee meets again in August. □

And secondly to maintain the direction of new initiatives introduced into the 1981 budget as a result of last year's domestic policy review of industrial innovation, even though at a reduced level.

In areas of project support, each field will be scaled downwards, although the emphasis will be maintained on shifting the balance of support back to physics and engineering from the life sciences. Thus the total for mathematical and physical sciences will be reduced by \$4.4 million (leaving a 14.5% increase over 1980), and for biological and behavioural sciences by (\$4.1 million, leaving a 6.8% increase).

The increase in funding for university-industry cooperative research projects will be reduced by \$5.1 million, from \$13 to \$7.9 million above this year's level of \$7 million. And support for small business innovation and industrial technology, initially scheduled to be raised from \$7.3 million to \$18.2 million, will now only increase to \$9.2 million.

Another new initiative to be cut back is the Ocean Margins Drilling Project. This is to be jointly funded with the oil industry, and had been scheduled to receive \$10 million in 1981, but the figure will be cut back to \$5 million.

More money has been saved by putting off detailed design studies of a 25-metre diameter millimeter wave telescope, which would have been scheduled for funding in 1982, as well as plans to purchase a new coastal research ship.

The NSF has also decided to defer a proposal to award \$14.3 million on a matching grant basis for improving university research facilities. There will also be a \$10 million cut in science education programmes.

Finally, the Foundation is cutting back on its joint scientific programmes with both the USSR and the China (the latter introduced for the first time in 1931). In particular, a programme with Soviet scientists on chemical catalysis, and a working group in scientific and technical information, will both be terminated, and these, together with cutbacks in exchanges through the National Academy of Science, will reduce the US/USSR budget from \$3.2 to \$1 million. Scientific cooperation with China will have its support reduced from a proposed \$2 million to \$1.5 million.

● **Defense Department:** the Department of Defense is the one agency to have escaped significant budget cuts. Precise figures have yet to be agreed, but it is expected that the department's original proposal will be cut back by between \$10 and \$20 million. This will still permit an increase in military support for basic research of about 15% — well above the expected rise in costs.

The big question now is how Congress will react. In general the cuts from its original budget proposals recommended by the administration are in line with those supported by Congressional budget committees, but there could be more surprises in store. □

Energy choices: the cultural assumptions

THE debate surrounding the report of the National Academy of Sciences Committee on Nuclear and Alternative Energy Systems (CONAES) continues to reveal as much about different perspectives on the energy problem as it throws light on possible solutions.

Latest contribution to this debate is the report of a panel set up by the committee to study the "lifestyle" implications of different projected energy scenarios. Published by the Academy last week, the report carries the emphatic message that "energy is a social, not a technological issue".

A society's demand for energy must be seen as part of its general organisation of preferences. Yet in many discussions of the factual basis of energy problems, the cultural and social contexts tend to be left implicit; and research on social and cultural factors influencing energy decisions has consequently received "remarkably little attention".

"We know something about the technology of energy, but much less about the agents: the experts, the interest groups, the public," says the report, which recommends that more research is needed on the social organisation of energy experts.

"Do nuclear physicists and engineers, for example, dominate the latecoming biologists, health physicists and social scientists?" it asks. "What is the relationship between the experts who estimate the probabilities of harmful events and those who assess their consequences?"

The panel which produced the report was chaired by Dr Laura Nader Professor of Anthropology at the University of California, Berkeley. In publishing it, the Academy points out that it is intended as a "supporting paper" to the full CONAES report, and that it has not gone through the "normal critical review" for such reports — although adding that it has been "subjected to a thorough and expert peer review for accuracy, consistency and clarity."

The bulk of the report concentrates on some of the possible implications of two future energy scenarios that might be expected in the year 2010. The first assumes a level of energy consumption in the US of 71 quads, equal to estimates of consumption in 1975 when the study was started.

This level of energy demand, says the report, could be achieved without any significant changes in attitudes, and would still involve increases in amenities, with improvements "roughly consistent with those that have occurred in recent decades."

The second scenario is based on the assumption that society agrees to cut its consumption to 53 quads — and is offered by the panel not as a prediction of what is likely to happen, but as a way of focusing on the relationship between energy demand and cultural values.

This scenario, says the panel, implies a significant shift in attitudes, including a decentralisation of work, and high value being placed on thrift and self-reliance. In what it characterises as a "high technology, low energy consumption" society, the aim would not be to turn back the clock, but to develop new technologies — such as advanced automobiles, or microprocessor building and process control techniques — aimed at improving the quality of life under the new energy constraint.

Pointing out that societies such as Sweden's already exist on much lower energy consumption than the US, the panel suggests that its scenario would be feasible, and would reflect the needs of a participatory democracy which might be challenged by increasingly centralised technological systems (such as those involved in the use of nuclear power).

"The trends toward tightly meshed technological systems characteristic of the 1970s are reversed in the 53 quad society, increasing the likelihood that most of the system can survive if a part of it is severely damaged," the report says.

In its conclusion, which stresses the need to integrate long-term energy planning with other kinds of social planning, the panel emphasises that there is nothing improper in the fact that political and social decisions about resource use extend beyond the market place and are influenced by subjective values and judgments.

"What is alarming is that experts often pretend to be able to perform objective analyses on energy systems or energy users because they are unwilling to acknowledge the values on which their decisions or analyses were made," it says.

Perhaps unsurprisingly, few of the more outspoken conclusions were included in the final report of the full CONAES committee. And this itself has provoked a reaction from Dr Nader, who says that her panel was told that its work "was not quantitative enough", and should include "more tables and less prose."

"The criticisms raised old disagreements about the use of qualitative and quantitative methods and illustrate how difficult it is in general for many scientists to incorporate findings from disciplines which could contribute to more intelligent discussions of unbounded problems" says Dr Nader. □

UK biotechnology

R&D attitudes wrong, says report

The "Spinks report" on the future of biotechnology in the UK was finally published last week. Robert Walgate reports

"THERE is a clear pre-development gap in R&D funding in Britain" Dr Alfred Spinks, chairman of a working party whose report* on UK biotechnology had just been published told a press conference last week. There is too little adventurousness, "a lack of gambling money". This is what is needed now for biotechnology in the UK, though it was clear that "one cannot transform the UK into an entrepreneurial state like California".

Dr Spink's report, prepared by the seven-man working party, says that "the present structure of public and private support for R&D is not well-suited to the development of a subject like biotechnology which, at the moment, straddles the divisions of responsibility both among government departments and among research councils and the arbitrarily defined fields of applied and fundamental research".

The recommendations and criticisms in the report are substantially the same as those included in a draft version detailed in *Nature* on 24 January (page 324). A joint committee for biotechnology should be set up to coordinate the biotechnical work of the five research councils, and a parallel interdepartmental steering committee set up for government departments.

Research councils should double their present commitment to biotechnology to a level of at least £3 million a year, and government departments should commit some £2.5 million. The National Enterprise Board and National Research Development Corporation should consider setting up a "research-oriented biotechnology company" with £2 million a year for five years.

John Ashworth, Chief Scientist at the Cabinet Office, who coordinated the working party, said "after five years we would expect industry to come in and invest in the company. If they don't, the venture will have failed."

"People are the main problem, not money" said Ashworth. The estimated spending on a biotechnical firm had included £1 million a year overheads, plus 50 scientists at £10,000 salary plus £10,000 research expenses. The 50 people could be found without difficulty, despite the increasing recruitment to foreign firms, thought Dr Spinks. "And we should also look abroad for talent".

The report supports the expansion of centres of excellence in the subject in universities. "A minimum of 20 new teaching and research posts should be created over the next five years with a capital investment of around £2 million" for lab facilities, says the report, and careful attention should be paid to the

training of an appropriate workforce.

● Professor Brian Hartley, a member of the Spinks working party, said last week that it was too late to consider setting up a firm to exploit British biotechnical talent, as recommended in the report.

Professor Hartley is a British member of Biogen, a US and Canadian-funded genetic engineering contract research body on which the UK firm, code-named 'Greenfields' by the National Enterprise Board, might be modelled. Biogen announced the cloning of interferon in the bacterium *E. coli* a few weeks ago, and completed a laboratory in Geneva last December; and recently it has been recruiting new staff.

The problem a new UK-based firm would face would be to find enough good staff," said Hartley. "A month ago they were available. Now they've joined us."

Hartley would not give precise figures. But "a few tens" have been recruited for the Geneva laboratory, to be compared with the 50 required for the UK firm. □

*Biotechnology, HMSO, £3

Crucial NEB decision due today

IF all goes according to plan, the UK National Enterprise Board (NEB) will today be taking a crucial decision on whether or not to seek ministerial approval to sink at least £10 million of public funds into British biotechnology.

The idea that the NEB should become involved in biotechnology receives impetus from last week's publication of the Spinks report which recommends that public funds be used to set up a research-orientated biotechnology company in Britain. However, the NEB were already investigating the possibility last summer. And last December, Mr Benjamin Lewin, editor of the journal *Cell*, was in the UK sounding out the opinion of British scientists on behalf of the NEB.

Although the details of the proposal are unclear, it is believed to favour both the establishment of a small specialist company and the funding of promising research in academic laboratories. In that way it might be possible to make the most of the proposed investment of £10 million, over a five-year period.

If the NEB decides to proceed with the British proposal, it is almost certain to have to seek approval from the Secretary of State, Sir Keith Joseph. Strictly speaking, the NEB would not need to do this because it was delegated the authority to invest up to £10 million by the Labour government which set it up in 1975. The Conservative government is less well disposed towards the concept of the NEB, (particularly

because it was often used to rescue the lame ducks of British industry) and is in the process of limiting its role and reducing to £5 million the sum it can invest without ministerial approval.

Likely recipients of any funds made available by an NEB-owned company would include the Agricultural Research Council's Plant Breeding Research Institute, the Imperial Cancer Research Fund laboratory in London and such Medical Research Council (MRC) laboratories as the Cell Immunology Unit in Oxford and the Laboratory of Molecular Biology in Cambridge. Within each of these laboratories there is considerable expertise on two of the techniques which underpin the current wave of biotechnology, namely genetic engineering through recombinant DNA techniques and monoclonal antibody production from hybrid cells.

Under pressure from the Treasury to take more seriously than it sometimes has done the possibility of commercially exploiting scientific discoveries made in its laboratories, the MRC has recently reminded its senior scientific staff of their obligation to draw to the Council's attention any results of commercial potential. In particular the MRC is interested in the distribution and marketing of monoclonal antibodies derived from hybrid cells by the technique devised in 1975 by Dr Caesar Milstein and Dr George Kohler in the MRC Laboratory

of Molecular Biology.

The potential market value of monoclonal antibodies and the lack of a satisfactory route for commercially exploiting them is well known to the MRC. At the end of February it asked its scientific staff to provide full information on the availability and characterisation of hybrid cell lines as they were produced. At the same time the MRC said that it was exploring the means by which such cells and the antibodies produced from them could be distributed and marketed in a coordinated way.

Questioned whether this represented a new departure in MRC policy, Dr James Gowans, MRC secretary, said that the policy was not new but that, under pressure from the Treasury, the possibilities of commercial exploitation were being looked at more aggressively. Many monoclonal antibodies produced in MRC laboratories are already being marketed through the small UK firm of Sera-Lab Ltd, with a proportion of the sales revenue being channelled back to the laboratories. But, said Gowans, the antibodies marketed by Sera-Lab tended to be those of marginal commercial value. For the development and marketing of antibodies of high commercial value either because of the anticipated volume of sales or because of the rarity of the cell hybrids from which the antibody was derived, Gowans would welcome the existence of a company of the kind that the NEB might start.

Peter Newmark

Spinks offers "too little"

THE chairman of Cetus Corporation, America's first and largest contract biotechnical enterprise, believes that £2 million a year for five years is far too little to invest in a new biotechnical firm — as envisaged in the Spinks report. Pressed as to what would be a reasonable investment, he suggested \$50 million over five years would be the minimum "if you are not to waste your cash".

The Cetus chairman, Dr Ronald Cape, was speaking at a conference on biotechnology in Rotterdam at the end of last month. He eschews government funding or work undertaken in universities outside Cetus's direct control. "We do our work in our labs" he said.

Returns will be long in coming, thinks Cape: no genuine profit for 5 to 10 years. Nevertheless, Cetus "is now investing millions of dollars of its own money, and comparable amounts on behalf of major company clients," in biotechnology.

New companies like Cetus will move biotechnology forward, thinks Cape, but new companies are not necessarily small. Cetus has 250 employees — "the largest collection of molecular biologists in the world" — and 18 projects in five industries, all with potential markets of billions of dollars. "Biotechnology is no longer cheap" says Cape. □

Two types of fermenter: cows outside ICI's single cell protein plant

Single cell protein organism improved

MICRO-ORGANISMS selected by the British firm Imperial Chemical Industries (ICI) to produce single cell protein (SCP) have been made more carbon-efficient by an application of recombinant DNA techniques, the firm announced last week.

ICI recently established the world's largest SCP fermenter — more than 50m high — using a methanol-consuming organism known as AS1. But the process has been under constant market pressure from agriculturally-produced soya-bean protein (both are used as animal feed supplements) and so ICI has been at pains to reduce the basic cost of its SCP. One obvious target was to improve the efficiency with which AS1 converts the costly methanol feedstock into protein.

Protein requires nitrogen, and AS1 gets its nitrogen from ammonia. But ICI discovered that AS1 assimilates the ammonia by an energy-inefficient pathway — one using the enzyme glutamate synthase to convert ammonia to glutamate. The energy for this comes ultimately from the oxidation of methanol to carbon dioxide, so the result is an excessive consumption of methanol.

But some organisms have a different pathway, using glutamate dehydrogenase, which is less able to scavenge small amounts of ammonia but is more energy-efficient (and thus carbon-efficient). The possibility thus arose that the glutamate synthase gene in AS1 could be deleted, and the glutamate dehydrogenase gene substituted for it.

Luckily the well-studied *Escherichia coli* has the right gene, and Dr John Windass of ICI Corporate Laboratory was able to excise its gene and insert it into AS1. The greatest problem turned out to be how to isolate an AS1 mutant which had a deletion in the glutamate synthase gene: such mutants die immediately. However, ICI discovered a temperature dependent mutation — one where the glutamate synthase fails to operate above 37°C — and

Windass inserted the dehydrogenase gene into this mutant.

Above 37°C this modified strain uses the dehydrogenase pathway for assimilating ammonia; and over a two-months period the strain has proved to be stable.

Dr Windass, speaking at a recent biotechnology meeting in Rotterdam, claimed that the engineered strain produced a "significant" improvement in carbon efficiency. Questioned whether a 3 to 5% improvement would justify the long toxicological studies that would be required if the strain was eventually to be employed, another ICI representative, Dr Peter Senior remarked that it would.

Toxicology studies are underway on the new strain, but it would be "at least five years" before it could be used. The strain could be adopted in the newly commissioned SCP plant, but there its efficiency would be sub-optimal, said Senior. "You have to design your plant around your bug".

In fact, Senior believes that the future of biotechnology will not be all plain sailing. "All the easy things have been done", he went on. "Biotechnology is grossly overselling its potential, and there is little likelihood on both scientific and economic grounds that we are staring a revolution in the face".

Conceptually the simplest biotechnical process was the growing and harvesting of single cell organisms, said Senior, yet "from my experience the single cell protein processes that have been developed at ICI have stretched the imagination and innovative skills of all those involved in their development to a degree that the conventional chemical industry has not experienced before".

The ICI single cell protein process was first envisaged in 1968; in 1976 a sum of £40 million was sanctioned for the construction of a large plant, which is now on the point of production.

Robert Walgate

United Kingdom

No conclusion on low level lead hazards

A government report, published last week, has provoked strong criticism from the lobby demanding reductions in the amount of lead added to petrol. The report, *Lead and Health**, concludes that lead in air is not the most significant contributor to lead contamination in people: food and water are more important. "In the vast majority of the population", it says, "airborne lead, including that derived from petrol, is usually a minor contributor to the body burden".

The working party on lead, set up in November 1979 under the Chairmanship of Professor P.J. Lawther, head of the MRC Toxicology Unit at St Bartholomew's Hospital, to prepare the report, concludes that it has only been able to satisfy one of the objectives required by its terms of reference — that of assessing the role of lead from petrol in relation to the other sources of lead in the environment. Its other aims — "to review the overall effects on health of environmental lead from all sources and, in particular, its effects on the health and development of children" — have been more difficult to achieve.

The toxicity of heavy exposure to lead is well known. The main controversy is over whether or not exposure to fairly low levels can effect health, especially the mental health of children. Several studies, in the US and Europe, suggest that children exposed to levels of lead which would not be high enough to result in the conventional signs of lead poisoning, have lower IQs and more behavioural problems than children who have not been exposed, or only very slightly.

The working party tried to meet the second part of its terms of reference by reviewing these studies. It concludes that there is no evidence of "deleterious effects at blood lead levels below about 35 $\mu\text{g}/\text{dl}$; neither is there any doubt about the serious consequence of blood lead levels above about 80 $\mu\text{g}/\text{dl}$; at intermediate concentrations, however, it says that the evidence is still very uncertain.

Many of the studies on the intelligence and behaviour of children are criticised in the report for not giving full details of their methodology. It says that in many of them, conflicting results have meant that the working party has not been able to come to any "clear conclusions concerning the effects of small amounts of lead on the intelligence, behaviour and performance of children". It recommends that further and more careful studies should be done: in particular better tests for examining intellectual function and behaviour in small groups of children are needed as is more research on the effects of pre-natal exposure on subsequent development.

Nevertheless, the report recommends

Professor P.J. Lawther, working party chairman

that children with blood lead levels above 35 $\mu\text{g}/\text{dl}$ should be followed up to identify the source of lead exposure.

Most cases of heavy contamination, the report concludes, are unlikely to result from exposure to unusually high concentrations of lead in air, although there will be local "hot spots" where airborne lead concentration are high and make a major contribution to overall body burden. Such areas should be identified and steps taken to minimise the hazard. The most likely sources of heavy exposure, however, are tap water, lead in paint and lead in imported cosmetics. The report recommends that a programme to detect lead in paint coatings accessible to young children be set up and that local authorities and water boards be encouraged to reduce lead in tap water in badly affected areas. The import and use of lead containing cosmetics should be discouraged, it says, and potential users should be made aware

of the hazard.

Other recommendations made by the report are the elimination of lead from manufactured foods — this is particularly a problem with canned foods — the development of guidelines for acceptable concentrations of lead in soil — more research also needs to be done on how plants take up lead from soil — and better education of the public on the hazards of lead especially to small children.

On the controversial topic of emissions of lead to the air from traffic, the report recommends that it should be progressively reduced and that the annual mean concentration of lead in air should be kept at less than 2 $\mu\text{g}/\text{m}^3$ in places where people spend a lot of time. Measures to achieve these limits may include "reduction of emissions, the relocation of industry or housing or traffic management schemes".

The report has been criticized by the anti-lead lobby. Parents Against Lead issued a statement at the time of the report's release saying that it had not taken into account evidence linking birth defects with lead contamination of the mother neither had it considered research already done showing that much of the lead in food comes from the air. To suggestions that the working party had been swayed by the oil industry, Professor Lawther said that each member of the party had their own scientific reputation to maintain and they had struggled to produce a fair scientific assessment of the subject.

Judy Redfearn

Lead and Health: the report of a DHSS Working Party on lead in the Environment HMSO £4.50

Dual support system for review

THE 'dual support' system whereby UK universities pay for buildings, services, technicians, basic laboratory equipment and salaries while research councils pay short-term grants for specific research is to be questioned by a new 7-man working party which will report ultimately to the Department of Education and Science.

The working party is "to review the current arrangements for the support of university research in the natural and social sciences". It is drawn from the Advisory Board for the Research Councils, which advises government on the allocation of the science budget among the research councils, and the University Grants Committee which provides universities with their basic running funds. The party will be chaired by Sir Alec Merrison, Chairman of the ABRC; other members include Dr Edward Parkes, Chairman of the UGC, and Sir Geoffrey Allen, Chairman of the Science Research Council (largest of the five research councils).

The feeling has been growing among the research councils that cut-backs in the UGC grant have fallen disproportionately on science, engineering, and medicine which through their laboratories have greater service requirements than the humanities. Applications to the research councils are increasingly including requests for equipment which would normally have been purchased through the university, and demands are increasing on research council central facilities (such as computers).

The working party will collect evidence, Sir Alec told *Nature* last week "and we can't rely on just a few scraps of information". On the other hand, the problem was too urgent to wait for the drafting and processing of a large questionnaire. The party "will not look at the total level of academic manpower" but will consider the problem of post-doctoral fellows and the provision of technicians.

"There is broad agreement that something is going wrong" with dual support

said Sir Alec. "We will have to balance saying something quickly with saying something reliable." The party hopes to report by the end of the year.

Meanwhile budgets for the research councils and the universities have fallen in real terms since 1978-9. Last week the UGC grant for the academic year 1980-1 was announced at £987 million, which says the Department of Education and Science "taking into account . . . the withdrawal of the subsidy for new overseas students . . . is about 2% lower in real terms than in 1979-80". The ABRC budget was also announced at £383 million for 1980-81 (see *Nature*, 3 April, page 000) with small increases for subsequent years, but these values are lower than those projected by the previous Labour government.

Jobs are also under pressure from these cuts, leading to a rapidly increasing average age for research groups; so it is hoped in some quarters that the terms of reference of the Merrison party will allow it to consider people as well as equipment.

● **EEC students to pay less:** The demand that foreign students must pay full tuition fees at British universities has been relaxed

for members of European Community countries, according to a report in *The Times*. This will increase pressure from Commonwealth countries (which account for half the UK's foreign students) that they also should get special treatment. The government is probably relying on the small number of EEC students in Britain remaining small, but, says *The Times*, it may have neglected the 3,500 Greek students who already outnumber EEC students. From 1981 Greece will be a member of the EEC and there may be an even greater inflow of students from the country.

● **£5 million for overseas student problem:** Mark Carlisle, Secretary of State for Education and Science, announced in the House of Commons last week that £5 million would be available in the academic year 1980-81 "to help ensure that uncertainty about prospective income from overseas students does not adversely affect selected postgraduate work of particular importance to this country". University sources last week had had no official indication of the meaning of this phrase.

Robert Walgate

Soviet Union

Media accuses US of war-mongering

US allegations about a bacteriological warfare incident at Sverdlovsk were met by the Soviet Union not merely with protests that the US was attempting to wreck the Geneva review conference on bacteriological warfare, but also by counter-allegations that the US was preparing itself for chemical war. In a major media campaign, the Soviet Union has cited sources ranging from *Newsweek* to "documents of the Church of Scientology" to support claims that the US is amassing "wet-eye" (nerve gas) and "dry eye" (stable toxic agent) bombs, carrying out experiments with toxic chemicals on US citizens, building up twelve arsenals of nerve gas, bacteriological aerosols, narcotics, defoliants and herbicides, while working on a "new generation" of binary gas chemical weapon "causing death in a matter of split seconds".

Much of the radio material, in both Russian and English, was beamed at the Third World. Special emphasis was given to alleged CIA experiments on "coloured people" in order to test the vulnerability of different ethnic groups. And a whooping cough epidemic of the mid-1960s in Florida, which resulted in 12 deaths, was specifically attributed to the CIA.

Nor was Britain exempt from such charges — it was attacked for alleged work on bubonic plague virus (citing the *Daily Telegraph*, training in the use of toxins at the army staff college (a "recent British TV film") and the new firing range near Porton Down (*Now!*), "officially, being used to devise protection against chemical warfare").

A few days after Tass's accusation, in the "Russian for abroad" service of Moscow radio, that the US are working, in "top-secret military laboratories", to "cultivate bacteria which could cause mass epidemics like anthrax, typhoid, plague, smallpox, etc", it had to elaborate on the official explanation of the Sverdlovsk incident. It said it was an outbreak of anthrax, caused by "adverse weather conditions in the autumn-winter of 1978-79" (which made sheep and cattle susceptible to contagious diseases), lack of personal hygiene in tending livestock, and the purchase of unbranded meat, wool and hides from unauthorized individuals. In spite of the struggle against the disease, it was explained, anthrax has never been completely eradicated from the Urals — thereby unfortunately providing a weapon for the US hawks to "call into validity [the bacteriological weapons] convention" and to "whip up the arms race".

Soviet Union

Academy stresses applied science

LAST November, Mr Brezhnev, in a major speech, charged the Soviet Academy of Sciences with greater responsibility for applied science and technology. Last month's annual general meeting of the Academy stressed that this new emphasis is well to the fore in its thinking.

How far this reflects a genuine change of direction is, of course, disputable. The Academy has already made it clear that it had been involved in applied research for some time before Brezhnev's speech. Nevertheless, the emphasis in this year's reports on the applied value of the Academy's work may be significant. President of the Academy Anatolii Aleksandrov, in his Presidential address, stressed particularly the work of the Shumyakin Institute of Bio-organic Chemistry, not only on protein structure, but also on genetic engineering, with, he implied, potential economic applications. He likewise commended the Academy's Institute of Microorganisms Biochemistry and Physiology for its work on artificial proteins for animal feed, based on oil products and natural gas, and in particular, the organic chemistry data bank established at Novosibirsk, which, he said, would enable scientists to develop new organic compounds with predetermined properties.

Physics and Geography Department of the Academy, Leonid Brekhovskikh outlined possible uses for the Soviet Union's glaciers and ice cover. His department, he said, had

devoted much time and resources to the study of glaciers as a fresh water source, since they contained "twice as much fresh water" as all the world's rivers and lakes. Ice could also, he said, be used as a building material in northern areas, when constructing port berths and laying roads.

From the newly exploited hinterland of the Baikal-Amur mainline railway, Academician Aleksandr Yanshin reported that after many years of forecasting and prospecting for potassium salts in Siberia, a major deposit, sufficient to ensure the "chemicalisation of agriculture in Siberia" had been located in the north of the Irkutsk oblast'. While Academician Aleksandr Fokin, Deputy Chief Academic Secretary to the Presidium, in effect summarised the tone of the meeting by stating that great attention was being paid to links between research and production.

To carry out this massive programme, the meeting was told, Soviet funding for science had been raised by 55% during the past seven years (while the number of scientists actively involved in research had grown by 50% to 1,300,000).

In his Presidential address, Aleksandrov also stressed that, to solve such global problems as the search for new energy sources and the exploration of space, international cooperation was essential. He censured the US administration for curtailing Soviet-American scientific ties and exchanges.

NEWS IN BRIEF

US produces draft climate plan

RESEARCH into the impact on the environment and society of increased carbon dioxide levels in the atmosphere, and into the effects of climatic change on world food production, are two of the top priorities that have been selected for attention under the draft of a National Climate Plan, published in Washington last week.

The plan presents a five-year programme for climate research, as required by the National Climate Programme Act of 1978. The carbon dioxide study has been selected as a "principal thrust" by the Department of Energy and the Department of Agriculture.

Also under the proposed climate plan, the National Aeronautics and Space Administration will give priority to efforts at understanding how the climate system gains and loses radiant energy. And the National Science Foundation will lead a major coordinated effort to understand the oceans' role in climate, in particular with heat-flux experiments planned in the Atlantic Ocean, perhaps leading to "a series of major international experiments in the late 1980s and early 1990s". The climate programme will coordinate the research efforts of all federal agencies, with the National Oceanic and Atmospheric Administration (NOAA) acting as the lead agency. NOAA's principal thrusts will be in the generation and dissemination of climate information and climate prediction.

US agency denies Agent Orange cover up

OFFICIALS of the Veterans Administration denied congressional charges last week that an official of the administration had referred to the herbicide 2,4,5-T as carcinogenic and mutagenic in a memorandum written in 1977. The charge had been made by two congressmen last month, who had obtained a copy of a memorandum with 'US government' written across the top, which said that the herbicide, known as Agent Orange, had been shown to "intercept the genetic DNA message process to an unborn fetus, thereby resulting in deformed children being born".

In producing the memorandum, the congressmen accused the administration of giving misleading information when it had earlier testified that there was no evidence linking the herbicide with human health problems. However, in a reply, Mr Max Cleland, administrator of the Veterans Administration, said that the VA official, whose telephone conversation was supposed to be the source of the memoran-

dum, had pointed out that it was "inaccurate in numerous points". Mr Cleland said that no-one in the VA had seen the memo before, and that it had been impossible to identify the author.

Australia orders Agent Orange inquiry

THE Australian government announced last week its intention to study the effects of Agent Orange, the dioxin containing herbicide used by the US to defoliate the countryside in Vietnam. Following a campaign by community and servicemen's groups, the government has granted \$2 million to survey the health of 41,000 Australian servicemen who were exposed to the chemical during the Vietnam war. In addition, the health of the families of the exposed servicemen will be studied. The study will be carried out by the Commonwealth Institute of Health of Sydney University. Veterans organisations have criticised the proposal saying that the survey will take too long to complete to prevent injury to those exposed. Mr K.G. Schultz, national secretary of the Returned Services League, said that a smaller sample would provide sufficient information about ill effects faster than the full survey. The Vietnam Veterans Action Association said it already had an overwhelming case for compensation with cases of birth defects that included missing limbs, club feet and cleft palates.

UK minister welcomes ASTMS cancer document

THE UK Secretary of State for Employment stated in parliament that he welcomed the Association of Scientific, Technical and Managerial Staffs document on occupational carcinogens (*Nature*, 20 March, page 203). In a written response to a parliamentary question by Renee Short asking if the government will take action "as a matter of urgency" on the document the minister said: "I welcome the initiative this union has taken in preparing the document, which I understand is to provide safety representatives and union officers with information. I propose to await advice from the chairman of the Health and Safety Executive before deciding whether discussions with the HSE or other interested parties are necessary".

UKAEA agrees PWR cracks a hazard

In a supplementary memorandum to the select committee on energy, the UK Atomic Energy Authority has agreed that the possibility of pressure vessel cracks

constitutes an insufficiently explored hazard of pressurised water reactors according to a report in *The Times*. The memorandum agrees with the analysis of Sir Alan Cottrell (*Nature*, 28 February page 803) that cracks as long as one inch could develop without detection in the pressure vessel which could lead to a rapid uncontrollable break resulting in a complete loss of coolant accident. Development of more advanced detection techniques than were previously thought necessary is required before the American design PWRs can be used in the UK. "It is vital that the necessary development work be undertaken as a matter of urgency" the memorandum is reported as saying.

In the meantime, Britain's ten year plan to introduce PWRs starting in 1982 may be delayed for another reason. The Nuclear Installations Inspectorate told the select committee last week that the Central Electricity Generating Board had yet to present its PWR design for safety clearance and to conclude a licensing agreement with Westinghouse. The delay, senior NII officials said, meant that the necessary safety studies could not be completed by the 1982 deadline.

In related developments, the Prime Minister is withholding approval for the construction of two scheduled advanced gas cooled reactors. The Prime Minister is a strong advocate of the PWR and has ordered further studies of the AGR proposal.

● Mr David Steel, leader of the Liberal Party, criticised Mrs Thatcher's "nuclear obsession" at the UK's largest ever anti-nuclear rally last week held on the anniversary of the Harrisburg accident. Fifteen thousand demonstrators from many British anti-nuclear groups attended.

Debendox safe, says UK committee

THE UK committee on the Safety of Medicines has found no evidence that the drug Debendox, an anti-nausea drug used by pregnant women, causes birth defects. The committee completed its third review of the drug at the end of last month. Two previous reviews in 1978 and 1979 had also found that the drug was safe.

Concern about Debendox has been stimulated by the recent court case in the US — where the drug is manufactured under the name Bendectin — which found that it had caused congenital abnormalities in a boy. The UK Minister of Health asked the committee to review its safety.

The committee has said that the level of abnormalities in the children of the 3,500,000 women who have taken the drug in the UK over the past 20 years, is no more than in the population as a whole.

NEWS AND VIEW

Is the Sun still shining?

from F.E. Close

THE conjunction of cosmology and particle physics as the result of recent developments in high energy physics formed the subject of a Wolfson Invitation Lecture given at the University of Oxford by J. Ellis of CERN. Taking as his title 'The very large and the very small' one of his themes was the current interest in neutrinos and how an understanding of their physics can provide explanations for some apparent anomalies in the Sun's interior.

Neutrinos are ghostly particles that carry no electrical charge and interact visibly only by means of the weak force. They are produced in stars, like the Sun, when light nuclei fuse to form heavy nuclei with consequent release of energy. They stream out from the Sun and can be detected on Earth by monitoring their reactions with atomic nuclei. In particular, their reaction with chlorine, which is readily available in ordinary cleaning fluids is used to calculate the incident neutrino flux.

When neutrinos interact with the ^{37}Cl nuclei in large underground tanks of cleaning fluid they initiate the reaction

by a neutron-proton conversion. The argon produced is extracted by helium purging, separated from the helium mass and finally introduced into a small proportional counter. Argon-37 undergoes K-capture decay with a 35 day period. Almost all these K capture events are detected and so the amount of argon is inferred and in turn the incident neutrino flux responsible for creating it in the first place can be calculated. This quantity is expressed in solar neutrino units (SNU). But although theoretical understanding of the Sun's interior requires that about 6 ± 2

SNU be observed, experiment has detected only a fraction of this. (A meeting in Rome during early February gave 2.2 ± 0.3 as the most up-to-date result).

One possibility is that our theoretical understanding of the Sun is badly wrong somehow. The next source of blame is in the inferences drawn from the experimental rate of detection.

Detection exploiting chlorine nuclei has several attractive features, not least of which is the abundant availability of cleaning fluid. However, a great disadvantage is that the transition can only be triggered by neutrinos that have at least 0.8 MeV energy. This is far above the maximum energy of neutrinos produced in $p + p \rightarrow d + e^- + \nu$ which is the main thermonuclear reaction in the Sun, and so the detection technique is insensitive to this important flux of neutrinos.

These low-energy neutrinos could be picked up through the nuclear transition from gallium-71 to germanium-71, which can be initiated by neutrinos with energies as low as 0.23 MeV. But to gain such information a target containing several tons of gallium would be required which is larger than the annual world production. Even were this region of the spectrum better studied however, it is thought unlikely that all the discrepancy with theory would be removed.

Another possibility is that the Sun has stopped shining. If the thermonuclear processes in the heart of the Sun have run down, there will be a significant drop in the neutrinos produced and a low flux will be detected on Earth. This is because the Sun is almost transparent to neutrinos and so they stream out from the core unhindered. In contrast, the Sun is quite opaque to photons and those that irradiate the Earth have come from the Sun's outer reaches. It would be some hundreds of thousands of

years before news of the changed circumstances in the Sun's core reached its surface. Thus we could be somewhere in this period, waiting for the surface photons to be turned off — the low neutrino flux is our advance warning of a real energy crisis.

Fortunately there is another possible cause for the low flux which is of particular interest in light of recent discoveries in particle physics.

Before 1976 two varieties of neutrino were known — one related to the electron (called electron-neutrino or ν_e), and one partnering the muon (muon-neutrino, ν_μ). Their masses are known to be orders of magnitude smaller than the lightest known particle (electron) and so it has been supposed that the neutrinos are massless. Since 1976 a third variety of neutrino has been discovered associated with the heavy lepton tau (τ). This ν_τ is less well studied but is also often referred to as 'massless'.

Masslessness and conservation principles are intimately linked, for example, the conservation of electrical charge is related to the masslessness of the photon. There is no conservation principle known that would require the neutrinos to be massless and so the possible consequences of their having masses have been studied.

If neutrinos have masses then the mass eigenstates could be linear superpositions of the ν_e, ν_μ, ν_τ eigenstates. Thus an electron-neutrino emitted in the Sun would be a linear superposition of three different mass eigenstates, each of which will oscillate with slightly different frequencies during the journey across space. By arrival at Earth a different linear superposition of mass eigenstates will be present which is equivalent to saying that what started out as ν_e is now a mixture of ν_e, ν_μ and ν_τ . If the mass differences are a few electron volts then the oscillations could be sufficiently rapid that the intensity of ν_e

arriving at Earth could be as low as 1/3 that which set out (the 1/3 being due to the three possibilities ν_e, ν_μ, ν_τ). This would naturally fit with the observed solar neutrino flux which is about 1/3 of that expected in the absence of oscillations.

The solar neutrinos produced in radioactive decays have a low energy. Higher energy neutrinos such as those produced in particle accelerators will have correspondingly larger oscillation lengths. As neutrinos can pass through the Earth without attenuation one could put detectors in line with a neutrino beam at CERN and see if the number of ν_μ , say, varies with distance.

One interesting theoretical development is the idea that all nature's forces could be unified at very high energies. Some versions of these theories predict that neutrinos have masses inversely propor-

tional to the unification scale. The unification is believed to occur at the order of the Planck mass (10^{19} GeV). This is large but not infinite and so the neutrino masses are small but not zero, of order 10^{-5} electron volts. If neutrino masses are indeed of this order then oscillation effects could be directly observable. In particular, the eccentricity of the Earth's orbit gives a natural variation to the distance that neutrinos have travelled *en route* from the Sun. Neutrino masses of the order of 10^{-5} eV could account for the solar neutrino anomaly, and provide an annual periodic variation in intensity of electron neutrinos which could be looked for. Such an observation would be exciting in its own right, would indirectly support attempts to unify the natural forces and would indeed resolve the solar neutrino anomaly, avoiding the catastrophic alternative. □

conditions produce new outer membrane proteins which act as receptors for Fe^{3+} -enterochelin (McIntosh & Earhart *Biochem.* **81**, 749; 1977). These organisms also contain altered species of tRNAs (Griffiths & Humphreys *Eur. J. Biochem.* **82**, 503; 1978). The same tRNA changes are found in *E. coli* recovered from the peritoneal cavities of lethally infected animals (Griffiths *et al.* *Infect. Immun.* **22**, 312; 1978). The alterations, which arise from an undermodification of the hypermodified nucleoside 2-methylthio- N^6 -(Δ^2 isopentenyl) adenosine in the tRNAs during growth under iron restricted conditions, may play an important part in regulating the expression of operons of the aromatic amino acid biosynthetic pathway from which enterochelin is synthesized by way of a branch pathway (Griffiths & Buck *Soc. Gen. Microbiol. Quart.* **7**, 10; 1979).

In a recent issue of *Infection and Immunity* (26, 925; 1979) P. Williams shows that *E. coli* carrying colicin V (Col V) plasmids possess another iron-sequestering mechanism, in addition to the enterochelin system, and suggests that this may be a contributory factor in the virulence of invasive strains. A well established link exists between Col V plasmids and the invasiveness of pathogenic *E. coli*. Most *E. coli* strains isolated from cases of bacteraemia in humans and domestic animals harbour Col V plasmids. Although the possession of a Col V plasmid markedly enhances virulence, colicin V activity itself is not essential (Binns *et al.* *Nature* **279**, 778; 1979; Quakenbush & Falkow *Infect. Immun.* **24**, 562; 1979). Williams finds that the possession of the Col V plasmid usually allows the bacteria to grow significantly faster in the presence of transferrin. However, this is not always the case. One Col V plasmid, which did not confer any growth advantage in conditions of iron stress, has been shown by Binns *et al.* to carry determinants for resistance to the bactericidal effects of serum. The acquisition of either characteristic, serum resistance or an enhanced ability to grow under iron stress, could confer a selective advantage on *E. coli* *in vivo*. The acquisition of both determinants would give an organism an even better advantage. It remains to be seen whether or not the plasmid in *V. anguillarum* mediates other virulence determinants in addition to enhancing the ability of the bacteria to grow in iron-restricted conditions.

The presence of a plasmid is not, of course, always required for virulence, nor is it the only factor involved. A further complication in the case of Gram negative pathogens is the natural variation in the O and K antigens of the bacterial cell wall. There is undoubtedly a connection between the structure of these complex polysaccharides, which determine serological specificity, and the virulence of the organism (Orskov *et al.* *Bact. Rev.* **41**, 667, 1977; Merson *et al.* *Infect. Immun.* **23**, 325;

Iron, plasmids and infection

from E. Griffiths, Henry J. Rogers & J.J. Bullen

AN important development in our understanding of bacterial infections has come from the realization that genetic determinants for certain virulence characteristics, such as haemolysins, toxins and adhesive factors, can be carried by plasmids. In this issue of *Nature* (page 566), J.H. Crosa reports on the presence of a plasmid in highly virulent strains of the fish pathogen *Vibrio anguillarum* which mediates a novel virulence mechanism, that of an efficient iron sequestering system. On losing the plasmid, *V. anguillarum* loses its virulence and also its ability to grow under conditions of iron restriction imposed by the serum iron binding protein, transferrin.

Several years ago it was found that iron compounds could abolish the antibacterial effects of body fluids *in vitro* and enhance bacterial virulence *in vivo*. These studies have led to an increased knowledge of the mechanisms of resistance to bacterial infection and have also provided an explanation for the changes in resistance which often accompany alterations in the iron status of the host (Bullen *et al.* *Curr. Top. Microbiol. Immun.* **80**, 1; 1978; Weinberg *Microbiol. Rev.* **42**, 45; 1978). We now know that although there is plenty of iron present in the body fluids of vertebrates, the iron content of human plasma for example is 20 μM , the amount of free iron is of the order of 10^{-18}M , which is far too low for bacterial growth. This extremely low concentration of free

iron is due to the presence of iron binding proteins, transferrin in blood and lymph and lactoferrin in secretions, with which the ferric ion is very strongly associated. Pathogenic organisms which multiply successfully under these conditions must possess mechanisms for assimilating protein bound iron or acquiring it from liberated haem.

Several organisms are known to produce iron chelating agents. *Vibrio cholerae*, for example, produces a phenolate iron chelator (Payne & Finkelstein *Infect. Immun.* **20**, 310; 1978) and *Pseudomonas aeruginosa*, iron chelators of both the phenolate and hydroxamate type (Liu & Shokrani *Infect. Immun.* **22**, 878; 1978). The best studied system, however, is that in bacteria of the genera *Salmonella*, *Escherichia* and *Klebsiella* which secrete the iron chelating compound enterochelin under iron restriction *in vitro*. This compound, which is the cyclic trimer of 2,3,-dihydroxybenzoyl serine, removes iron from iron-binding proteins and it has been proposed that its secretion is essential for growth of the organisms *in vivo* (Rogers *Infect. Immun.* **7**, 445; 1973). Recently, Griffiths and Humphreys (*Infect. Immun.*, in the press) have shown that enterochelin is produced *in vivo* during fatal infections with *E. coli*. Yancey *et al.* (*Infect. Immun.* **24**, 174; 1979) have reported that the loss by mutation of the ability to synthesize enterochelin greatly reduces the virulence of *Salmonella typhimurium* and also inhibits its ability to grow in human serum. In addition to secreting enterochelin, *E. coli* growing under iron-restricted

E. Griffiths, Henry J. Rogers & J.J. Bullen are at the National Institute for Medical Research, London.

1979). There are *E. coli* strains for example which belong to classically recognized enteropathogenic serotypes that are non-toxicogenic and non-invasive according to the usual criteria, and do not seem to harbour virulence plasmids but which nevertheless do cause severe disease (Levine *et al. Lancet* **I**, 1119; 1978; Scotland *et al. FEMS Microbiol. Lett.* **7**, 15; 1980; Ulshen & Rollo *New Engl. J. Med.* **302**, 99; 1980). In an era when resistance to known antibiotics seems to be increasing we clearly need to know far more about the mechanisms of microbial pathogenicity and host resistance. Although good progress is now being made, it is more than likely that the versatile bacterium still has many more surprises in store for us. □

X-ray astronomy with the Einstein observatory

from J.L. Culhane

NASA's Einstein X-ray observatory satellite was launched in November 1978. It carried a large reflecting X-ray telescope, of a few arc seconds angular resolution, equipped with various focal plane detectors for X-ray imaging and spectroscopy. Before its launching, X-ray astronomy had made spectacular advances through observations undertaken with satellites instrumented by US, UK and Netherlands research groups. These missions established the existence of several hundred X-ray sources and discovered a range of exciting phenomena that included the presence of rotating neutron stars and perhaps even black holes in binary star systems, the existence of high temperature gas spread throughout clusters of galaxies, the identification of Seyfert galaxies as X-ray sources and the heating of interstellar plasma to million degree temperatures by the shock waves that expand from supernova explosions. However with the exception of the small X-ray reflectors on the Copernicus satellite, and the modulation collimators on SAS-3, Ariel V and HEAO-1, all of these missions used collimated proportional counter detectors with fields of view of several square degrees. Thus it was to be expected that the availability of a truly imaging telescope with arc second resolution would bring about a transformation in our knowledge of the X-ray sky.

A preliminary measure of this transformation is provided in a recent issue of *Astrophysical Journal Letters* (234, L1-L81; 1979) which contains 15 papers devoted to the first results obtained with

the Einstein satellite. The observing programme included many specific objects but, because of the two orders of magnitude improvement in sensitivity over previous instruments, it was also decided to use the telescope for deep surveys of several regions of the sky that contained no previously known X-ray sources. Regions in Draco and in Eridanus have been studied and 43 new sources identified. Ten of these are believed to be extragalactic, the majority probably quasars and on the basis of an extrapolation to lower fluxes, the contribution of such sources to the diffuse X-ray background is established as almost 40%. If the majority of these sources were indeed quasars and active galaxies, then on the basis of our current understanding of X-ray to optical luminosity ratios, quasars brighter than $B \sim 20.3$ mag could account for essentially all the X-ray background. If confirmed by future observations, this could prove to be one of the most significant discoveries made by Einstein. Quasars are in fact established as a class of luminous X-ray emitters by the detection of more than 30 where only 3 X-ray quasars were known before the Einstein mission. Many more are being found as observations continue.

It has been known for some time that the giant radio galaxy, Centaurus A, has an X-ray source located in the nucleus of the associated active galaxy. Observations with the Einstein telescopes have now established that in addition to the point X-ray source coincident with the infrared nucleus, a diffuse component associated with the inner radio lobes, an emitting region of about 4 arc min extent surrounding the nucleus and an X-ray jet lying between the nucleus and the NE inner radio lobe are also present. The paper which reports these discoveries suggests that the radio lobe component may arise from the inverse Compton scattering of the microwave background while the existence of a jet provides further evidence of the continuing supply of energy to the lobes from the nucleus. This observation of X-ray structure around the nucleus of the best studied giant radio galaxy could be of the utmost importance in helping us understand the energy supply mechanism for radio galaxies in general.

The extended sources of X-ray emission associated with clusters of galaxies have naturally been objects of much interest to the Einstein observers. Several papers are devoted to results on the structure and evolution of these sources. However one of the most striking observations has been the detection, from the neighbourhood of M87 in the Virgo cluster, of an emission line characteristic of ionized oxygen (hydrogen-like O^{+7}) by the focal plane crystal spectrometer. The detection of highly ionized iron (Fe^{+24}) emission lines by the Ariel V and OSO-8 satellites in the X-ray spectra of several clusters had previously established the presence of high temperature ($30 \times 10^6 \text{ K} < T < 120 \times 10^6$

K) plasma in these sources. However the detection of material around individual galaxies at temperatures less than 10^7 K has important implications for theories of gas infall and cooling in clusters. More recent observations with both the crystal and solid state spectrometers have indicated a similar situation near NGC 1275 in the Perseus cluster and we await further observations of the gas near massive galaxies in other clusters with considerable interest.

The Uhuru and Ariel V surveys indicated the presence of many X-ray sources in the plane of our galaxy thus suggesting that similar objects should exist in other normal galaxies. A dramatic measure of the advance due to Einstein is provided by the detection of 69 discrete and 7 diffuse sources in the nearby spiral galaxy M31. This is all the more striking when we recall that the Uhuru catalogue listed M31 as a single X-ray source with an intensity that was only just detectable. Thus the enormous power of a high resolution imaging telescope is clearly demonstrated. Similar advances have been made in observations within the galaxy. A group of six point sources has been found in the neighbourhood of Cygnus X-3 where previously only the latter was known to exist while the existence of more than 20 sources has been established in the Orion nebula. Work in progress at the Harvard Centre for Astrophysics which has been reported at a recent conference in Boston although not presented in the Einstein issue of *Astrophysical Journal*, suggests that X-ray emission has been detected from essentially all of the star classes represented in the H-R diagram. Thus X-ray astronomy has in less than two decades advanced from a concern with a small number of unusually energetic objects to occupy a position of central relevance for the entire field of astrophysics.

While the discovery of X-ray emission from a large number of stars is of considerable importance, a hint of the real potential of X-ray astronomy is provided by the beautiful emission line spectrum of the Capella system that has been obtained with the solid state spectrometer. X-ray emission lines from Mg, Si, S and Fe are observed and it is at once clear that the deployment of high resolution X-ray spectrometers will allow us to apply the sophisticated plasma diagnostic techniques, that have been refined over many years in observations of the solar corona and of laboratory plasmas, to the study of the detailed physics of a wide range of objects. The importance of X-ray spectroscopy is further emphasized by the X-ray emission line spectrum of the supernova remnant Cassiopeia A, which when compared with the detailed map of the remnant obtained with the imaging detectors, permits a considerable increase in our understanding of these objects.

Although the Einstein observatory has carried out a series of truly staggering observations in its first year of operation,

one cannot help but feel a slight disappointment that as yet nothing has emerged to rival in excitement the discovery of X-ray emitting binary systems and clusters of galaxies by the Uhuru satellite. So far no faint new categories of X-ray objects have been discovered. However to complain is merely to emphasize the extraordinarily high standards that have been set in the subject from the beginning. We are witnessing the establishment of a mature astronomical discipline which, along with optical and radio astronomy, must from now on have an essential role in our study of the Universe. The manner in which the Einstein mission is bringing about this maturity will surely come to be regarded as one of the substantial achievements of twentieth century astronomy. □

Exploiting papyrus

from Peter D. Moore

THE potential of papyrus (*Cyperus papyrus*) to 'clean up' tropical lakes in danger of eutrophication (see *News & Views* 276, 560; 1978) is again under review. In particular work by Gaudet (University of Nairobi) on Lake Naivasha in Kenya provides grounds for optimism.

Papyrus forms floating swamps in the peripheral zones of tropical lakes especially where incoming rivers debouch their waters (Gaudet *Aquatic Bot.* 3, 1; 1977). The plant is robust (up to 5 m tall) and productive, so considerable quantities of nutrient ions are absorbed during swamp growth. Gaudet (*Ecology* 58, 415; 1977) made some preliminary estimates of nutrient uptake based on certain fairly simple assumptions concerning the rates of culm replacement within a papyrus stand. He concluded that rates of uptake could amount to N, 62 kg m⁻²; P, 5 kg m⁻²; K, 103 kg m⁻² during one complete turnover of culm replacement (147 days). Nutrient losses would occur at the same time as a result of death, decay and leaching of older culms. Losses were considered to amount to two thirds of the material absorbed, the remainder accumulating within the swamp peat which descends from the floating mat to accrete with the other sediments below.

When inflow is high, water will move faster below the floating raft and will dilute the ionic concentration in this zone. On the other hand, in dry periods the concentration beneath the raft will rise as a result of evaporation. Fast through-flow could, of course, reduce the efficiency of the swamp in modifying water quality. Gaudet has monitored these effects through the year at Lake Naivasha (*Verh. Int. Verien Limnol.* 20, 2202; 1978) and has indeed shown such seasonal variations.

Peter D. Moore is a Senior Lecturer in the Department of Plant Sciences, King's College, London.

The overall nutrient trapping efficiency of the swamp, however, was low as a result of the rapid water movement in wet periods. The final retention of nutrients in the sediments below the mat was of the order of 10% for magnesium, ranging down to 1% for calcium. So overall, the swamp is not greatly influencing water quality.

These figures may not fully reflect the precise operation of the process, however, because of the particular analytical techniques used. All water samples were filtered before chemical analysis, which would have removed organic particulate matter. Gaudet has now published additional data (*J. Ecol.* 67, 953; 1979) based on the use of sediment traps, and has expressed these as a percentage of annual input retained in the sediment. On this basis, the removal of elements is of the order P, 57%, S, 59%; Fe, 83%, Mn, 94%. So the swamp is acting as an efficient nutrient extractor, but much of the extracted material is being transported as detritus by the flow-through below the mat.

Nitrogen is an important exception, for there is a high degree of net fixation within the swamp system. Net gains within the ecosystem suggest fixation rates in excess of 50 g m⁻² annum⁻¹.

The efficiency of papyrus swamps as nutrient extractors would be increased if they were harvested periodically and the biomass removed. Thompson (in *The Nile, biology of an ancient river* (ed. J. Rzoska) 177, Junk, The Hague, 1976) has found that a stand of papyrus contains a mixed population of culms of various ages, with the life cycle of a culm taking about 150 days. Gaudet has shown that rapid accumulation of nutrients occurs in the early stages of growth; thus frequent cropping should result in a maximum nutrient drain on the system.

Thompson, Shewry and Woolhouse (*Bot. J. Linn. Soc. Lon.* 38, 299; 1979) have now conducted a detailed analysis of the population structure and productivity of papyrus culms in swamps of the Upemba basin of Zaire and in Uganda. The total biomass of the system seemed to be climatically determined, being 2.9 kg m⁻² in Uganda (545 m altitude), 1.1 kg m⁻² in Zaire (~1000 m) and 3.4 kg m⁻² at Gaudet's Lake Naivasha, Kenya (1830 m). But there was not such a strong, nor such a consistent variation in productivity between these areas; figures ranged between 10 and 35 g m⁻² day⁻¹. Some temperate reedswamps, such as *Scirpus lacustris* in Germany (*Westlake Biol. Rev.* 38, 385; 1963) have been described which overlap the lower end of this range, but these figures do emphasize the high productivity of *Cyperus papyrus*, which is considered by Thompson *et al.* to be a C₄ species.

So papyrus harvesting could provide a renewable energy resource for combustion at the same time as enhancing its efficiency in recovering nutrients from eutrophicated

Cyperus papyrus

waters. Work of the sort described here emphasizes the need to conserve tropical swamps until their full value can be assessed and until appropriate management regimes can be developed on the basis of controlled experimentation. Their value for local human populations could be considerable and their exploitation could relieve pressure on other, less easily renewed, ecosystems. □

Atomic hydrogen stabilized

from P. V. E. McClintock

SILVERA and Walraven's report (*Phys. Rev. Lett.* 44, 164; 1980), that they have succeeded in stabilizing bulk atomic hydrogen, suggests that the preparation of superfluid hydrogen may become a practical proposition in the not too distant future.

Superfluids, possessing the remarkable facility of frictionless flow behaviour, devoid of the viscous effects which characterize familiar liquids such as water, are exceedingly rare. The only examples known at the moment are the liquid heliums (⁴He below 2 K; ³He below 2 mK) and, in a slightly different sense, the electron gas in a superconducting metal. Thus if hydrogen and also, perhaps, its isotopes deuterium and tritium could be prepared in a similar state it would, at a stroke, double the number of superfluids accessible to experimental investigation.

This exciting possibility rests on the fact that, although ordinary molecular hydrogen (H₂) forms a solid at low temperatures, and is thus unable to become superfluid, no such restriction applies in the case of atomic hydrogen (H). The forces between a pair of hydrogen atoms depend profoundly on whether their electron spins lie mutually parallel or

P. V. E. McClintock is in the Department of Physics at the University of Lancaster.

antiparallel. In the latter case, there is a very strong force of attraction, rapidly leading to formation of an H_2 molecule. In the former case, on the other hand, the interatomic force is so weak that it is possible, at least in principle, to cool a dense assembly of H atoms to the very low temperatures where superfluidity may be expected to manifest itself, without solidification occurring at all. The main difficulty, of course, is that of getting atomic hydrogen into a stable spin-aligned state, given that it has a very strong natural inclination to minimize its energy by forming H_2 .

Although Silvera and Walraven have followed the conventional approach of attempting to stabilize the H gas by a combination of high magnetic field and low temperature, their apparatus incorporates a number of novel and imaginative features. The atomic hydrogen itself was produced in the usual way by means of a discharge tube at room temperature but, rather than allowing the H gas merely to diffuse into the stabilization cell, they pumped it in using a specially designed vapour diffusion pump which, using helium as the working medium, possessed a unique capability in being able to operate at 0.48 K. This device was an essential feature of the overall experimental design because, as the same authors demonstrate in the paper immediately following (Walraven & Silvera *Phys. Rev. Lett.* **44**, 168; 1980), the H gas would otherwise have had a strong tendency to leak out of the stabilization cell again.

The authors also found that it was essential to cover the walls of the cell with a very thin layer of helium-4. Because hydrogen is insoluble in liquid helium, this coating served to insulate the H atoms from contact with the walls which, if it had occurred, would have produced spin-flips rapidly followed by recombination to ordinary molecular hydrogen.

A special type of bolometer was developed to demonstrate the presence of the H gas confined within the cell. This exploited the heat of recombination which is generated when H_2 is formed: after a controlled burning off of its helium coating, the bolometer provided an active surface on which recombination could take place. An estimate of the initial H density could be made by noting the extent of the recombination heating which occurred when the bolometer was triggered in this way. It was found that, after being filled, the cell could be left a period of several minutes without any measurable loss of H at all, implying that, at least within the timescale of the experiment, their stabilization scheme had been completely successful. The greatest density of H achieved was estimated as being not less than 1.8×10^{14} atoms cm^{-3} ; but the authors hope to be able to improve on this figure by several orders of magnitude (a factor of 10^3 or 10^6 being needed before the superfluid

effects would be expected), once they start trying.

These experiments represent a most encouraging step forward. They have raised the status of superfluid hydrogen from little more than a scientific pipe dream to being a very real possibility within the next few years. □

Are abundant proteins less variable?

from Yvonne Edwards & David A. Hopkinson

THE analysis of enzymes using gel electrophoresis and specific activity stains has revealed extensive genetic diversity in man and other species. At least 25% of the genes which determine enzyme structure are variable and the average level of heterozygosity per gene locus detectable by conventional unidimensional electrophoresis is in the region of 7 to 10% in man and other vertebrates and somewhat higher in insects such as *Drosophila* (Harris *et al. Ann. Hum. Genet., Lond.* **36**, 9; 1972). However, recent studies on the same species using the O'Farrell bidimensional gel electrophoresis technique (*J. biol. Chem.* **259**, 4007; 1975) suggest that the average heterozygosity at gene loci determining the particular array of proteins discernible by this procedure is about 1 to 4%, substantially lower than expected from the enzyme surveys. Are the data from the uni and bidimensional electrophoresis compatible?

The bidimensional technique provides a method for the analysis of proteins which occur in greater abundance than most of the enzyme proteins since it relies on non-specific protein staining or autoradiography. The proteins are denatured and separated by isoelectric focusing in the first dimension according to charge and by SDS gel electrophoresis in the second dimension according to molecular size. A large number of gene products can be analyzed in a single experiment, but side-by-side comparison of the complex patterns of several hundred spots is difficult and the identification of individual variation is not as straightforward as in the unidimensional electrophoresis of enzymes. However, two recent studies (McConkey *et al. Proc. natn. Acad. Sci. U.S.A.* **76**, 6500; 1979; Walton *et al. J. biol. Chem.* **254**, 7951; 1979) on the polypeptides of human fibroblasts are noteworthy since they elegantly solved the problem of side-by-side comparison by using a double label autoradiographic technique which permits

the simultaneous analysis of 3H -labelled and ^{14}C -labelled proteins in the same gel. Between 300 and 400 polypeptide spots from human fibroblasts were examined and the average heterozygosity was found to be in the region of 1%. Estimates of average heterozygosity lower than expected from enzyme surveys were also found in bidimensional electrophoretic analyses of smaller samples of *Drosophila* (Leigh Brown *et al. Proc. natn. Acad. Sci. U.S.A.* **76**, 2381; 1979) and mouse polypeptides (Racine *et al. Nature* **283**, 855; 1980).

The reasons for the apparent discrepancy between the results obtained by the different techniques are not clear, but there are two major lines of argument worth exploring. Either the polypeptides accessible to analysis by the bidimensional procedure derive from a class of proteins with genetic properties distinct from those of soluble enzymes or this method is not as efficient at detecting variant proteins as conventional electrophoresis.

Bidimensional analysis selects those polypeptides present at highest concentrations, but this feature almost certainly does not account for the apparent low incidences of genetic variation. On the contrary, there is good evidence that the relative abundance of a protein and levels of heterozygosity at particular gene loci are not directly related, for example amongst human proteins present at high concentration haemoglobin, carbonic anhydrase II and several of the serum proteins show genetic polymorphism. And more recently, extensive genetic heterogeneity of the major storage protein of *Pisum*, demonstrated by both uni and bidimensional analysis, has been reported (Casey *Heredity* **43**, 265; 1980).

However, the array of proteins analyzed by the two procedures differ not only in their relative abundance, but also in their subcellular origin. In the bidimensional system whole cells, tissues or organisms are solubilized by denaturation, so that many of the most abundant proteins are derived from structural components such as membranes and are very likely to have complex subunit structures. It can be argued that vital protein-protein interactions and associations between protein and lipid/carbohydrate moieties such as occur in membranes, place constraint on the number of mutations which can occur. Furthermore, it is now recognized that multimeric proteins involved in polypeptide interactions show less genetic variation than monomeric proteins (Harris *et al. Proc. natn. Acad. Sci. U.S.A.* **74**, 698; 1977; Zouras *Nature* **262**, 227; 1976; Ward *Biochem. Genet.* **15**, 123; 1977) and it is possible that multimers may be over-represented in the array of proteins analyzed by the bidimensional procedure.

Considering the question of efficiency there is a considerable body of evidence which testifies to the discriminatory power

Yvonne Edwards and David Hopkinson are at the MRC Human Biochemical Genetics Unit, University College, London.

of the bidimensional method. Milman *et al. Proc. natn. Acad. Sci. U.S.A.* **23**, 4589; 1976) detected a mutation for the enzyme hypoxanthine guanine phosphoribosyl transferase by analysis of HeLa cell extracts, Commings (*Nature* **277**, 28; 1979) has reported a polymorphism of human brain polypeptides, and genetic variants of transferrin, recognized by conventional electrophoresis were demonstrated after bidimensional analysis (Anderson *et al. Biochem. Biophys. Res. Commun.* **88**, 258; 1979).

In all cases, the variants detected by the bidimensional procedure can be attributed to mutational events leading to a change in charge on the protein molecule. Many of the variants detected by conventional electrophoresis are also attributed to amino acid substitutions leading to a change in net charge and there is good reason to think that the affected residues lie on the surface of the protein. However, this type of charge change variant is more readily detected after electrophoresis of the native protein than of the denatured polypeptides, since in denaturing conditions the frictional resistance of the molecules is greatly increased and the charge change less exposed. Nevertheless, it is interesting to note that Steinberg *et al. (Cell* **10**, 381; 1977) have demonstrated that progressive carbamylation of AMP dependent protein kinase leads to discrete shifts in *pI* detectable by the bidimensional procedure, which presumably represent single charge changes. However, one of the problems associated with detecting amino acid modifications by isoelectric focusing is that the efficiency of the resolution, as judged by the relative shift of *pI*, will not be the same over the whole gel, but will depend upon the position in the *pH* gradient and the proportional change in charge.

One way in which this problem could be overcome is by modification of the conditions for bidimensional electrophoresis which is commonly carried out in a broad *pH* gradient and at standard gel concentrations. So far the possibilities for varying these conditions have scarcely been explored and it seems likely that if greater flexibility is introduced then somewhat higher levels of heterozygosity might be revealed.

In contrast, the unidimensional gel electrophoresis method provides many opportunities for manipulating conditions such as *pH*, buffer ions, gel concentrations, solvent polarity, temperature and sample concentration. Effects due to the incorporation of affinity ligands in the gels and interactions with sulphhydryl reagents can also be explored. And it is quite a common experience that analysis of an enzyme in a range of electrophoretic conditions leads to the identification of additional variants and an increased estimate of heterozygosity. On the face of it the unidimensional electrophoretic methods primarily detect

charge change variation, but in practice the procedure almost certainly demonstrates a range of other types of variants which arise as a result of uncharged amino acid replacements. Such variants may be revealed

by differences in affinity of the allozymes for coenzymes, variable interaction with different buffer ions and altered electrophoretic mobility due to conformational distortion. □

Growth hormone: deletions in the protein and introns in the gene

from M. Wallis

MODERN high resolution fractionation methods can reveal that most protein preparations are made up of several different closely-related species. In the case of pituitary growth hormone, such microheterogeneity has a multiplicity of origins, and its detailed analysis has provided a wealth of information about the biochemistry and genetics of the protein. Thus, heterogeneity at the N-terminus of bovine growth hormone is now known to be a consequence of ambiguous processing of the precursor (pregrowth hormone) while heterogeneity at residue 127 reflects an allelic variation in the population of cows from which the hormone is prepared. In the case of human growth hormone various enzymically modified forms of the protein have been described, which may reflect enzymatic processing of the hormone *in vivo*.

Perhaps the most interesting of the many growth hormone variants, however, is a form isolated from human pituitaries and characterized by U.J. Lewis and his colleagues at the Scripps Clinic, La Jolla (*J. Biol. Chem.* **253**, 2679; 1978); this they have called 20K human growth hormone, since it has a molecular weight 1000-2000 less than normal human growth hormone (22K). The 20K variant is smaller because it lacks 15 amino acid residues found in the normal form of the hormone. The precise position of this deletion has now been shown (Lewis, Bonewald & Lewis, *Biochem. Biophys. Res. Commun.* **92**, 511; 1980) to include the entire sequence between positions 32 and 46 (inclusive) of the polypeptide chain; otherwise 20K is identical to the normal form of human growth hormone. The variant possesses growth-promoting activity similar to that of normal human growth hormone, but lacks the insulin-like activity normally associated with the hormone. It exists in all human pituitaries, comprising about 15% of the total growth hormone content.

How is this remarkable variant formed? A clue may be provided by recent work on the structure of the growth hormone gene by H.M. Goodman and his colleagues at the University of California, San Francisco (Fiddes *et al. Proc. natn. Acad. Sci. U.S.A.* **76**, 4294; 1979). They have shown that the gene is split and contains at least

M. Wallis is in the School of Biological Sciences, University of Sussex.

three intervening sequences (introns). One of these occurs between the codons for residues 31 and 32 in the mRNA — precisely the position of the start of the deletion in 20K. The end of the deleted sequence (between residues 46 and 47) does not correspond to the position of another intervening sequence, but it is noteworthy that the last two bases of the codon for residue 46 (glutamine) are AG (Martal *et al. Science* **205**, 602; 1979), a base sequence found almost universally at the 3' end of an intervening sequence in the primary RNA transcript of a gene (Crick *Science* **204**, 264; 1979). It is difficult to believe that this partial correspondence between a deleted sequence in the protein and an intervening sequence in the corresponding gene is a coincidence. It seems likely, therefore, either that 20K represents the product of a duplicated gene in which an intervening sequence has been lengthened to include part of a coding sequence (exon) or that the messenger RNA for 20K is produced from the same primary RNA transcript (and therefore the same gene) as normal human growth hormone, which would therefore be processed in two different ways. In the second case, a region of the primary RNA transcript that is a coding region for normal human growth hormone would be treated as part of an intervening sequence for the 20K variant, and different ways of processing a single primary RNA transcript would lead to production of two different proteins.

Whichever of the two explanations is correct, it is difficult to avoid the conclusion that the occurrence of an intervening sequence in a gene has allowed the formation of a markedly different protein variant. Gilbert (*Nature* **271**, 501; 1978) has proposed that the existence of intervening sequences may allow large changes in protein structure, and this may well be an example of such a change. It is interesting in this connection that the rate of evolution of human growth hormone is much greater than that of the non-primate hormones (Wallis *Biol. Rev.* **52**, 35; 1975). Whether the potential benefit of such large evolutionary jumps is in itself sufficient to explain the occurrence of intervening sequences, or whether other causes led to their origin and the evolutionary jumps are a consequence of their existence, remains to be seen. □

Caenorhabditis Genetics Center

A *Caenorhabditis* Genetics Center (CGC), sponsored by the National Institute on Aging, is being established at the University of Missouri. The CGC will be responsible for acquisition, banking, and distribution of *C. elegans* strains and reference strains of other *Caenorhabditis* species. Related services will include maintenance and annual distribution of the genetic map of *C. elegans*, coordination of genetic nomenclature, and maintenance and distribution of a bibliography of research publications.

The centre is the only one planned for *Caenorhabditis elegans*, an organism that has attracted attention in recent years as a research model for genetics, neurobiology, and developmental biology as well as aging.

The establishment of a *Caenorhabditis* Genetics Center (CGC) will promote the rapid and orderly accumulation and documentation of the genetic wealth of *C. elegans* for the benefit of all types of biomedical research on this organism. The genetics of *C. elegans* already enjoys important advantages over more traditional genetic systems. The ability to freeze stocks permits the reliable preservation of all known mutant types. The ancestry of virtually all strains is known so most stocks can be accurately described. A uniform system of genetic nomenclature has been instituted. Since most genetic data have been accumulated in only a few laboratories, the centralization of these data is feasible.

The specific goals of the CGS are (1) to establish a reliable and accessible genetic stock repository, including represent-

ative mutant alleles of all characterized genes as well as chromosome rearrangements, (2) to coordinate and publicize a uniform genetic nomenclature, (3) to coordinate and publicize the delineation of the genetic map, and (4) to develop a computer-based data storage and retrieval system which will handle bibliographic information and data used to generate the genetic map, as well as descriptive data on mutant strains.

The CGC strain collection will include at least one allele of each identified gene, all available chromosomal rearrangements, and available closely linked double mutants, as well as other strains useful for genetic mapping. Laboratories providing mutants of *C. elegans* will be requested to include such information as name of strain; names of contained mutation(s); mutagen used; whether the strain was backcrossed and, if so, how many times; genes affected by the mutation(s); map location(s) of mutation(s); and data used to determine map locations.

C. elegans strains will be available without cost to all qualified investigators pursuing genetic and/or related studies with *C. elegans*. The Center will not be fully operational until the Fall of 1980, but some services are available now. Inquiries should be addressed to: Dr. Margaret M. Swanson, Curator, or Dr. Donald L. Riddle, Director, *Caenorhabditis* Genetics Center, Division of Biological Sciences, Tucker Hall, University of Missouri, Columbia, Missouri 65211.

Though the types vary considerably, many of the contexts from which they come are of high status, being predominantly rich burials. In addition a number of objects combine iron with a precious metal, such as iron rings with a covering of sheet gold or an iron pin with a gold head. It is clear that iron was being increasingly used in societies with a highly developed competence in metallurgy, frequently but not exclusively in association with objects of high status. Analyses have so far been few, but many of these early iron objects have been considered meteoric on the grounds of their high nickel content. There has been some controversy over objects with a rather lower percentage of nickel, but there can be no doubt that throughout the period, and increasingly towards the later phases, terrestrial ores were also being exploited.

Similar evidence of an early origin for iron-working has also come from other areas. Some of the most exciting archaeological discoveries of recent years have been made at Ban Chang in north-east Thailand. In addition to surprisingly early occurrences of agriculture, irrigation and copper metallurgy, iron was in use by at least 1600 BC. As Gorman and Charoenwongsa (*Expedition 18*, 14; 1976) show, iron was used especially for the blades of bronze-handled weapons found in rich graves. In China, iron was similarly used in a composite bimetallic weapon in a rich grave of the Shang period at K'ao-Cheng, perhaps around 1200 BC. As Chang (*Archaeology of China*, 351; 1977) points out, there too the iron may be of meteoric origin since other comparable weapons, now in western museums, have been proved to be so.

In Europe too, reports of early iron have increased considerably in recent years. Brongers and Woltering (*Prehistorie van Nederland*, 97; 1978) describe finds of iron and slag with radiocarbon dates as early as the 12th century BC, while an iron fragment from a knife found in Slovakia is dated to 1465±35 BC (Butler in *IX Congress UISPP, Résumé*, 431; 1976). Another line of evidence has been followed by Bouzek, who has studied the technology of the decoration of bronzes in the late bronze age (*Zeitschr. f. Archäol.* 12, 9; 1978). He found that iron tools were increasingly used from 1100 BC, a conclusion now supported by the discovery of the appropriate iron tools in contemporary graves. The only detailed regional study is by Laszlo (*Acta Archaeol. Hung.* 29, 53; 1977), who documents recent discoveries in Romania, where iron became progressively more common through the later bronze age from 1200 BC onwards, copying the local bronze forms and even being manufactured in the same workshops as bronze.

All these regions share a number of common features such as the pre-existence of a developed metallurgical technology, the copying of bronze forms in iron, the large proportion of iron objects which are

The early development of iron-working

from T. C. Champion

TRADITIONAL explanations for the adoption of technological innovations in archaeology are being called into question by recent research. Much attention has been paid to the origins of metallurgy, and to the possibility of multiple independent inventions of copper working, but until recently the development of iron working had been relatively ignored. Recent work now suggests that the discovery of iron did not occur in one unique area from which its knowledge was diffused, that early iron was not superior to bronze, and that bronze-using communities did not adopt it immediately. Instead, what has usually been regarded as an obvious technological advance appears, when seen against the background of current economic and social conditions, to be due to much more complex reasons.

The traditional view held that the technology of iron was developed only in the Near East and was guarded as a royal

T. C. Champion is in the Department of Archaeology, University of Southampton.

monopoly by the Hittite empire during the second millennium. The collapse of the empire about 1200 BC allowed the knowledge of iron-working to spread to other areas where the new material was progressively adopted as its potential for making superior weapons and tools was appreciated. This view was based as much on the interpretation of Hittite historical documents as on archaeological finds but recent work by Waldbaum (*Stud. Mediterr. Archaeol.* 54, 1; 1978) now shows it to be untenable. Iron was known and used regularly throughout the area of the eastern Mediterranean from the early bronze age onwards and though some finds are known from as early as the beginning of the third millennium they become much more common in the mid-second millennium. Tools, weapons and jewelry are all made in iron. As the forms are in most cases specifically local ones which copy pre-existing bronze examples it would seem that iron was worked locally rather than imported from a single centre.

of high status, and in many cases the use of iron in combination with other metals. A rather different picture is presented in India, where Chakrabarti (*Antiquity* 50, 114; 1976) has argued for an independent growth of iron-working by 800 BC. Here, however, the range of iron goods is predominantly domestic, and a phase of gradual development has yet to be documented. It is possible that the earliest stages of iron-working in the subcontinent have yet to be explored as the date of 1025 \pm 110 BC reported by Jain (*Prehistory and Protohistory of India*, 191; 1979) for a layer containing small iron tools would support the suggestion of a more extended development. Even more problematical is the question of the origin of iron in west Africa. The technology described by Tylecote (*W. Afr. J. Archaeol.* 5, 1; 1975) from the Nok culture of Nigeria is already well developed by about the fourth century BC, too early to be derived from any of the known industries of the north-east in Egypt or the Sudan. The solution proposed is that the technology diffused from the north coast across the Sahara but the possibility of independent invention cannot be ruled out. There was no previous tradition of metallurgy but the ready availability of high-grade ores and the pyrotechnic skill demonstrated by the Nok clay figurines fulfil some of the necessary preconditions.

The theory of a unique invention of iron technology is clearly now very difficult, if not impossible, to maintain, and the focus of research has moved from questions of diffusion to the conditions under which the technology developed. Although the west African case still remains problematic, the other areas all shared a competent bronze metallurgy and in most of them the use of early iron is strongly associated with high status objects. The development of iron technology may therefore be seen as taking place in stratified societies where considerable technological resources are invested in producing prestige items. This stage of early development is quite distinct from a later phase when iron replaces bronze for a wide range of everyday items. Snodgrass (*Dark Age of Greece*, 213; 1971) argued, on the basis of limited analyses of early iron objects, that they were in fact not superior to the quality of bronzes but actually inferior and he attributed the wide-scale adoption of iron in Greece to an interruption in the supply of raw materials forcing the use of local resources. Maddin, Muhly and Wheeler (*Scient. Amer.* 237, 122; 1977) have described the discovery of the essential techniques of carburization, quenching and tempering in the Near East, but they too, like Waldbaum, ascribe the demise of bronze to a breakdown in the supply of raw materials, especially tin. Further analyses are needed of both iron and bronze objects, but it is now recognized that the problems of the discovery and adoption of iron can only be understood in relation to contemporary social and economic conditions. □

Ocean trench topography

from D.L. Turcotte

THE anomalous topography and negative gravity anomalies of ocean trenches are readily explained by plate tectonics. The oceanic lithosphere bends and descends into the interior of the Earth in a process referred to as subduction. This sounds relatively straightforward until one realises that the oceanic lithosphere is a 100 km thick plate made up of cool, brittle rock. How can a plate 100 km thick made up of a brittle material be bent through an angle of 45° or more in the subduction process?

Two recent papers examine alternative hypotheses for the bending behaviour of the lithosphere. Chapple and Forsyth (*J. geophys. Res.* 84, 6729; 1979) argue in favour of an elastic-perfectly plastic rheology. In the upper 20 km they assume that the rock is relatively weak due to low lithostatic pressure (the weight of the overlying rock) and postulate a yield stress of 1 kbar. In this region the tensional bending stresses due to the flexure of the lithosphere at an ocean trench give the normal faulting earthquakes observed seaward of many ocean trenches. Between depths of 20 and 50 km a yield stress of 6 kbar is postulated. At stresses less than 6 kbar the rock is assumed to behave elastically and then yields freely when the yield stress is reached. This is the definition of an elastic-perfectly plastic rheology. It is this part of the lithosphere which transmits the high stresses associated with the bending. At depths greater than 50 km temperatures are assumed to be sufficiently high that thermally-activated creep processes (that is, dislocation creep) relieve the elastic stresses. Predicted trench topography agrees well with observations.

The primary objection to the application of the elastic-perfectly plastic rheology is the high stress level required. Many seismologists object to high stresses (greater than a few kilobars) in the lithosphere. Seismic studies indicate that the stress drops in most large earthquakes are of the order of 100 bar or less. Stress fields derived from the surface strain associated with earthquakes give similar values. On the other hand, scientists who study the mechanical behaviour of rock in the laboratory tend to favour high stresses. Mantle rocks tested in the laboratory can easily be stressed to 5 kbar without failure. Extrapolations of laboratory derived friction laws and creep studies also give high stresses in the lithosphere.

An alternative approach to the problem of the bending of the oceanic lithosphere at ocean trenches has recently been given by Melosh and Raetsky (*Geophys. J.* 60, 333; 1980). These authors postulate that the oceanic lithosphere is made up of a near-

surface elastic layer with a thickness of 15–30 km overlying a highly viscous layer 50–80 km thick. The shape of the bending lithosphere is primarily attributed to the viscous flow in the lower lithosphere. The viscous flow is attributed to solid-state creep. Again good agreement with the observations is obtained. The maximum stress required is a few hundred bars.

The principal advantage of the viscous rheology is the lower required stress level. However, the derived viscosities of 2×10^{22} – 10^{23} poise are quite low, being less than an order of magnitude larger than the viscosity associated with solid-state creep in the deeper mantle. This does not seem to be consistent with the temperature dependence of thermally activated creep processes.

It is clear that comparisons with observations at oceanic trenches cannot differentiate between the elastic-perfectly plastic and elastic-viscous hypotheses. The alternative rheologies must be applied to other flexure problems. Examples include the flexure of the lithosphere under the load of oceanic islands, the load of sediments, and the load of mountain belts. It is implicit in the viscous analysis that bending stresses will relax with time. Whether the resultant deformation of the lithosphere when subjected to a fixed load can be observed is also a subject of controversy.

An understanding of the bending behaviour of the lithosphere under load will help in our understanding of how stress is transmitted through it. An essential part of this understanding is the stress level present. At present the stress level at depth in the lithosphere is uncertain by more than an order of magnitude. Only when we understand the state of stress in the lithosphere will we be able to start to understand in some detail why earthquakes occur. □

100 years ago

BAUMGARTNER, the inventor of a navigable balloon, having three cars attached, each with ten or twelve wings, set in motion by a crank, has attempted an ascent at Leipzig. On the rope being cut the balloon rose very slowly, skimming the house-tops, whereupon the two assistants jumped out of the centre car in alarm. The balloon shot up to a great height, then burst and fell. Baumgartner was not seriously hurt, and is resolved on a second experiment.

REVIEW ARTICLE

Peptidergic neurones

Tomas Hökfelt, Olle Johansson, Åke Ljungdahl, Jan M. Lundberg
& Marianne Schultzberg

Department of Histology, Karolinska Institutet, S-104 01, Stockholm 60, Sweden

More than 20 peptides have been identified in neurones of the brain, spinal cord and periphery. In several cases a peptide occurs together with a 'classical' transmitter in the same neurone. This raises new questions about the process of neurotransmission and may have important implications for our understanding and treatment of mental disorders.

It is generally accepted that nerve impulses are transferred either from one neurone to another or to an effector cell by chemical neurotransmitters released at the neuronal synapses. In 1963, McLennan¹ listed seven chemically identified putative transmitters including acetylcholine (ACh), γ -aminobutyric acid (GABA) and monoamines such as noradrenaline and dopamine. As, crudely speaking, neurotransmitters act in only two ways—to excite or to inhibit the postsynaptic cell—seven candidates seemed more than sufficient. Therefore, the recent discovery that many peptides also seem to act as transmitters in the nervous system^{2,3} has evoked both interest and doubt.

Doubts arise not only about the need for more than 20 peptide neurotransmitters, given that one excitatory and one inhibitory transmitter should be sufficient to operate the nervous system, but also because 'classical' transmitters have always been small molecules (molecular weight ~ 200), whereas some of the peptides consist of up to 30 or more amino acids (MW $\sim 3,000$). Furthermore, many peptides now identified in the brain were previously thought of as peripheral hormones, such as angiotensin II^{4,5} and members of the gastrin/cholecystokinin (CCK) family^{6,7}. Even some of the large pituitary hormones, prolactin, adrenocorticotrophic hormone (ACTH), thyroid stimulating hormone (TSH) and growth hormone, and also the pancreatic hormones insulin and glucagon, may be present in brain (see ref. 8). But the idea of a compound being both a hormone and a neurotransmitter should not be so surprising as we have long accepted such a dual role for noradrenaline⁹.

The realisation that mammalian neurones produced and released peptides followed du Vigneaud's characterisation of oxytocin and vasopressin as octapeptides¹⁰. These two hormones are released into the blood in the posterior pituitary from the end of neurones which originate in the supraoptic and paraventricular nuclei of the hypothalamus. These neurones, previously described by the Scharfers, Bargmann and others¹¹ as neurosecretory, magnocellular neurones, were thus the first peptide neurones identified in the mammalian brain. The next peptide neurones to be discovered were those containing the three hypothalamic hormones, thyrotropin releasing hormone (TRH), luteinising hormone releasing hormone (LHRH), and growth hormone release-inhibiting hormone (somatostatin)^{12,13}. These neurones are also hypothalamic in origin, they also secrete their content into blood vessels and are therefore also neurosecretory. Neuroanatomically these systems have been assumed to correspond to the parvocellular tuberoinfundibular neurones described by Szentagothai *et al.*¹⁴.

The major impetus for the study of neurones containing either the hypothalamic peptide hormones or the host of other chemically identified peptides came when the peptides became available in amounts sufficient for production of antibodies. This made it possible to measure peptides in tissues and body fluids by radioimmunoassay¹⁵ and to localise peptides at

the cellular and ultrastructural level using immunocytochemistry.

It is important to realise that, whereas a transmitter role seems well substantiated for a few peptides, crucial experimental evidence is lacking for many others, and additional functions of neuropeptides, as trophic factors or factors involved in long-term events, should be considered. It is, however, not the aim of this review to discuss the evidence for peptides as transmitters (see refs 16, 17). Instead, we shall concentrate on the morphology and distribution of some peptide systems, as revealed by immunocytochemistry, and what this may tell us of possible functions. Of particular interest has been the discovery of peptides in neurones which also contain a classical transmitter such as noradrenaline, serotonin (5-HT), dopamine or ACh¹⁸. This is a situation similar to the one seen in certain endocrine cells, which belong to the APUD (amine precursor uptake and decarboxylation) system as defined by Pearse¹⁹ and which store both a peptide hormone and a biogenic amine, further underlining the close relationship between the endocrine and nervous systems.

The immunohistochemical technique

Immunohistochemistry²⁰ has evolved as an extremely useful technique for visualising different types of compounds in nervous (and other) tissues^{21–23}. In principle any substance can be traced provided that (1) it is available in pure form, (2) it is immunogenic (or can be rendered immunogenic by conjugation to carrier protein) and (3) it can be retained in tissue sections during processing for immunohistochemistry. In addition to this 'universal' applicability, this method has the advantage that it can be combined with other types of histochemical techniques. Furthermore, 'double-staining' techniques^{24,25} allow visualisation of more than one substance in a given section.

With the immunohistochemical approach antisera raised against peptides conjugated to carrier proteins such as bovine serum albumin, are applied to tissue sections and visualised by fluorescent or other types of markers. Various modifications can be used: the classical indirect immunofluorescence technique of Coons and collaborators²⁶; the peroxidase technique²⁷; and the sensitive peroxidase–antiperoxidase (PAP) technique²⁸. Apart from limitations of sensitivity, and the limited ability of the antibodies to penetrate to intracellular storage sites, the major problem is the specificity of the immunological reaction. Thus, an antiserum may not only react with the proper antigen but also cross-react with structurally similar peptides. Hence the cautionary use of terms such as 'substance P immunoreactive' and 'substance P-like immunoreactivity'. Future research may show that, when multiple systems are described with a particular antibody, they are not homogeneous with regard to their peptide content. Thus, for example, of the more than 30 groups of

Fig. 1 Schematic drawing of a neurone demonstrating some differences between a neurone using a 'classical' transmitter such as noradrenaline (left) and a peptide transmitter (right). SER, smooth endoplasmic reticulum.

substance P immunoreactive cells found in the rat central nervous system (CNS)²⁹, perhaps only a fraction of them contain the genuine undecapeptide³⁰.

The complexity of this problem can be well illustrated by the opioid peptides³¹⁻⁴⁶. Hughes *et al.*³¹ originally discovered two pentapeptides—Leu- and Met-enkephalin—but by now several other larger opioid peptides have been shown to contain one or other of these pentapeptide sequences³¹⁻³⁶. Using antisera to Leu- and/or Met-enkephalin, many groups have described the central cellular localisation of 'enkephalin' neurones³⁷⁻⁴⁴. Because of the problem with cross-reactivity, it was not possible to decide whether the two pentapeptides were present in separate or in the same neurones, and only recently have Larsson *et al.*⁴⁴ provided evidence that Leu- and Met-enkephalin neurones constitute separate systems. It remains to be established to what extent the 'enkephalin' neurones contain the pentapeptides, as opposed to the large opioid peptides from which, in some cases, they are likely to be derived. It is clear, however, that a separate β -endorphin system exists in the rat brain^{45,46}.

A further problem with the immunocytochemical mapping of peptide neurones comes in visualising peptides in the cell soma and axon. This is probably because they contain peptides either in low concentration or in precursor form. In the latter case an antibody cross-reacting with a precursor is an asset rather than a hindrance. Thus, using one of our somatostatin antisera, cell bodies can easily be identified by means of a strong immunoreaction localised in the Golgi apparatus⁴⁷. This particular antibody is known to cross-react with a probable precursor molecule⁴⁸ and it is tempting to speculate that the Golgi-associated somatostatin-immunoreactive pool represents the precursor. Another approach for visualising peptides in cell somata is the use of colchicine, a drug which inhibits axonal flow^{49,50} and in this way increases peptide levels. Peptides in axons may be detected by ligation of nerves⁵¹ and the resulting accumulation of the peptide.

Some characteristics of peptide neurones

Only limited information is available on the structural, biochemical and physiological properties of peptide neurones. Nevertheless, it seems that they do not have unique characteristics which would allow their identification on pure morphological grounds. Peptide neurones may be small or large, multipolar or pseudo-unipolar, their nerve endings may make morphologically defined synapses or they may act on receptors over 'long' distance and they may have long or short projections. Nor does ultrastructural analysis reveal any fine structural features exclusively characteristic of peptide neurones. One feature that is common to several classes of peptide neurone is the large granular vesicle⁵², a type originally described in peripheral adrenergic neurones⁵³.

Although functional evidence suggests that at least some peptides act as neurotransmitters^{2,3,16,17,54}, the method of replenishment of peptide neurotransmitters to nerve endings seems to be different from that of classical neurotransmitters (this difference is shown schematically in Fig. 1). For example, intraneuronal noradrenaline levels are kept fairly constant by the efficient replacement of released transmitter by (1) enzymatic synthesis in the nerve endings, (2) re-uptake from the extraneuronal (synaptic) space through an active membrane mechanism and (3) supply of amine in storage vesicles (or their precursors) from the cell body via axonal transport⁵⁵. Peptides, on the other hand, are probably produced only on the ribosomes of the cell soma, possibly in the form of a larger precursor molecule⁵⁶ without local synthesis in nerve endings. As no reuptake mechanisms seem to operate for peptides in nerve endings, every single peptide molecule released from a nerve ending must be replaced by axonal transport. This comparatively inefficient and slow mechanism should be reflected in the dynamics of synaptic events at peptide synapses⁵⁷. Perhaps peptides are released intermittently rather than tonically. Such an intermittent release may, however, be 'compensated' for by a long duration of action. The amounts of peptide released may also be much smaller than those of classical transmitters. This would be in line with the rather low concentrations of peptides found in the CNS (~1,000 times less than monoamines and 100,000 times less than amino acids). Furthermore, peptides may activate receptors at much lower concentrations than the classical transmitters, a situation which may compensate for an 'inefficient' replacement of released transmitter (see below).

Distribution of peptide neurones

Early studies both with radioimmunological and immuno-histochemical techniques indicated that the three hypothalamic hormones—TRH, LHRH and somatostatin—were present outside the median eminence and even outside the hypothalamus. The finding of these neurosecretory products, previously assumed to be exclusively involved in pituitary control, also in, for example, the spinal cord was followed by reports of the presence of so called gut hormones such as vasoactive intestinal polypeptide (VIP)⁵⁸⁻⁶⁰ and CCK⁶ in many areas of the brain. A hypothesis has since emerged according to which the central and peripheral nervous systems and the endocrine system have a number of peptides, or perhaps families of peptides, in common⁶¹. Although differences can be observed between various species, the occurrence of peptide-containing neurones is widespread.

Central peptide neurones

More or less extensive maps of the many central peptide systems have been published: for immunoreactive substance P^{29,62}, enkephalin³⁷⁻⁴⁴, neurotensin⁶³, CCK⁶⁴⁻⁶⁶ and bradykinin⁶⁷. Although they overlap in many areas, each central peptide system has a unique distribution pattern of cell bodies. For example, although both substance P and enkephalin immunoreactive cell bodies have been described in more than 30 areas of the CNS, they overlap only slightly and, when present in the same nuclei, the cells do not seem to be identical.

Fig. 2 Immunofluorescence micrographs of four serial sections incubated with antiserum to TRH (a), LHRH (b), somatostatin (c) and tyrosine hydroxylase, a marker for catecholamine neurones (d). All four substances are present in the median eminence (me) close to portal vessels (arrows), but with clearly different distribution patterns indicating their occurrence in separate neurone systems. Note dense plexus of somatostatin in nerve fibres also outside the median eminence in the arcuate nucleus (asterisks) suggesting a transmitter role. Of these four systems only the dopamine neurones have their cell bodies in the basal hypothalamus (d). V, ventricular. Scale bar, 50 μ m (from ref. 181).

Coexistence of two peptides has, however, been described. Immunoreactive ACTH and β -endorphin are present in the same neurones in the hypothalamus⁶⁸⁻⁷⁰, and recently we have observed TRH-like immunoreactivity in substance P (and 5-HT) immunoreactive neurones of the medulla oblongata^{18,71}.

It is clear from the data collected so far, that some areas of the brain are rich and others are poor in peptide-containing neurones. The hypothalamus, the amygdaloid complex (particularly its central nucleus), certain nuclei of the medulla oblongata and the dorsal horn of the spinal cord are examples of areas of the rat brain where most peptides can be found. In the cerebellum, on the other hand, only scattered peptide fibres are observed. The cerebral cortex seems to lack many peptides but is rich in somatostatin-, VIP- and a gastrin/CCK-like peptides, all present in interneurones⁷². Of particular interest are the median eminence of the hypothalamus and the dorsal horn of the spinal cord.

The first immunohistochemical identification of a small peptide in neurones was of LHRH-immunoreactive fibres observed in the external layer of the median eminence of the hypothalamus⁷³⁻⁷⁵. TRH and somatostatin fibres were also later found in this brain region (Fig. 2). Lesion studies suggest that these three peptides do not originate in the basal hypothalamus, as assumed originally, but deeper within the hypothalamus⁷⁶. Instead, the arcuate neurones with short projections to the median eminence seem to contain small classical transmitters such as dopamine⁷⁷, GABA⁷⁸ or ACh⁷⁹, which may exert part of their action at the median eminence level rather than being released into portal vessels. It may be, therefore, that a set of short tuberoinfundibular dopamine, GABA and ACh neurones act as a type of 'gating system', controlling the release of hypothalamic hormones into the portal vessels via an axo-axonic influence⁷⁶.

The dorsal horn of the spinal cord receives a complex input of peptide-containing neurones as seen in Fig. 3. Immunoreactive substance P, somatostatin, VIP and gastrin/CCK are present in primary sensory neurones^{65,80,81}. Substance P (and perhaps somatostatin) is also observed in propriospinal neurones or spinal interneurones^{29,82}. Whether the supraspinal substance P/5-HT neurones, which descend to the ventral horn⁸³, also project to the dorsal horn is not yet firmly established. A descending enkephalin-immunoreactive system⁸⁴ may also project to the dorsal horn. Neurotensin⁶⁴ and enkephalin^{38,85} are present in interneurones (or possibly propriospinal neurones). These findings suggest that peptides play an important part in the processing of sensory information at the spinal level.

Peripheral and sensory peptide neurones

The wide distribution of peptides in peripheral neurones has now been firmly established. Initial observations concerned substance P in primary sensory neurones⁸⁶⁻⁸⁸, but this and other peptides are also present in virtually all parts of the autonomic nervous system, particularly the gut and certain autonomic ganglia. There are well documented examples of primary sensory neurones containing immunoreactive substance P, somatostatin⁸⁹, VIP⁸¹ and gastrin/CCK^{65,81}. It is not yet absolutely clear whether these peptides can ever occur in the same neurones, but substance P and somatostatin at least do not⁸⁹. Substance P-like immunoreactivity has also been observed in the vagus nerve^{81,90-94} and in taste neurones of the cat⁹⁵. Thus, substance P may be involved in sensory processes of various types, including pain⁹⁶.

If substance P is a transmitter substance in primary sensory neurones one might expect its main action to be exerted at the central branches in the spinal cord or brain stem. A role for

Fig. 3 Schematic illustration of a spinal ganglion and the dorsal horn of the spinal cord and some of its peptide systems. Note that substance P (SP) probably is present in three, possibly four different systems: (1) primary sensory neurones; (2) interneurones or propriospinal neurones; (3) descending systems, some of which may contain both SP and 5-HT. AII, angiotensin II; ENK, enkephalin; G, gastrin/CCK; NT, neurotensin; SO, somatostatin; VIP, vasoactive intestinal polypeptide. In the dorsal horn there are other peptide and non-peptide systems, not mentioned here (from ref. 80).

substance P in the periphery has, however, long been suspected, for example in the axon reflex inducing antidromic vasodilation⁹⁶⁻⁹⁸. Recently, Olgarth *et al.*⁹⁹ have demonstrated that substance P can be released from peripheral, presumably sensory, branches in the tooth pulp. Interestingly, more than 90% of the substance P immunoreactive material produced in the nodose ganglion (of the vagus system) seems to be transported into the peripheral branch⁹⁴. All these findings suggest that substance P may have an important function at its sensory terminal branches by, in fact, acting at 'postsynaptic' cells or perhaps by modulating the threshold of 'its own' nerve ending. The occurrence of substance P in presumptive taste neurones also indicates other possibilities. It is well known that the structural integrity of the taste buds is dependent on their sensory innervation¹⁰⁰. Transplantation experiments have shown that different types of sensory ganglia, even lumbar sensory ganglia, can induce taste bud formation^{101,102}. In all these ganglia substance P is present. Could it be that this peptide is of trophic importance for the structural integrity of the taste buds?

Autonomic ganglia: Autonomic ganglia, particularly prevertebral sympathetic ganglia in the guinea-pig, contain networks of peptide immunoreactive fibres (Fig. 4). Thus, the inferior mesenteric ganglion has dense plexuses of enkephalin¹⁰³ and VIP¹⁰⁴ immunoreactive fibres and in addition substance P¹⁰⁵, gastrin/CCK and bombesin (ref. 65 and our studies, in preparation) positive fibres are present. A few somatostatin-immunoreactive fibres are also seen¹⁰⁶. Ligation and transection experiments have revealed that some, at least, of these peptides are present in separate systems (ref. 80 and Lundberg *et al.*, in preparation). Thus the enkephalin-immunoreactive fibres

Table 1 Examples of neurones and endocrine cells containing both a classical transmitter and a peptide

Classical transmitter	Peptide	Area (species)	Refs
Serotonin	Substance P	Medulla oblongata (rat)	83, 134-137
Serotonin	TRH	Medulla oblongata (rat)	18, 71
Serotonin	Substance P + TRH	Medulla oblongata (rat)	18, 71
Noradrenaline	Somatostatin	Sympathetic ganglia (guinea pig)	106
Noradrenaline	Enkephalin	SIF-cells (cat)	138
		Sup. cerv. ganglion (rat)	103
		Adrenal medulla (many species)	138, 139
Noradrenaline	Neurotensin	SIF-cells (guinea pig, cat)	103, 138
		Adrenal medulla (cat)	138
Noradrenaline	Somatostatin	Adrenal medulla (man)	140
Adrenaline	Enkephalin	Adrenal medulla (many species)	138-140
Dopamine	Enkephalin	Carotid body (cat, dog, monkey)	141
Dopamine	CCK	Ventral tegmental area (A9, A10) (rat, human)	18, 142
Acetylcholine	VIP	Autonomic ganglia (exocrine glands) (cat)	143, 144

Fig. 4 Schematic illustration of some peptide systems connecting the inferior mesenteric ganglion with other parts of the nervous systems (guinea pig). There may in addition be a gastrin/CCK projection from the gut to the ganglion (from ref. 80).

represent preganglionic neurones, the substance P-immunoreactive ones are of a sensory nature, the VIP and gastrin/CCK fibres probably originate in the gastro-intestinal tract, whereas the somatostatin fibres have their origin within the ganglion itself. Some peptide projections could very well correspond to neurones first described by Kuntz¹⁰⁷ and recently investigated by Kreulen and Szurszewski¹⁰⁸ and assumed to be involved in reflexes between enteric mechanoreceptors and

sympathetic prevertebral neurones. Of particular interest are the presumably sensory fibres containing substance P, which may represent collaterals from axons on their way to the gut. A similar arrangement has been proposed for the nervous supply of the nasal mucosa¹⁰⁹. If substance P is released from such collaterals, this could explain the need for a considerable transport of substance P into the peripheral branches of the sensory neurones (see above). In this context it is of interest that Krier¹¹⁰ has demonstrated that substance P increases the excitability of nerve cells in certain sympathetic ganglia.

Gastro-intestinal tract: Peptide neurones containing immunoreactive substance P¹¹¹⁻¹¹⁴, VIP¹¹⁴⁻¹¹⁶, somatostatin^{114,117,118}, enkephalin^{37,114,119,120}, neurotensin¹¹⁴, gastrin/CCK^{65,114} and bombesin¹²¹ have been identified in the gastro-intestinal tract. Analysis of neurones stained consecutively with different antibodies has revealed that substance P, VIP and enkephalin are present in separate systems¹¹⁴. In the proximal colon the somatostatin- and gastrin/CCK-like peptides coexist in some neurones, although separate somatostatin and gastrin/CCK neurones seem to exist¹¹⁴. Most of these peptide systems are intrinsic to the gut¹¹⁴, but morphological and functional analysis is complicated by the fact that the same peptides are also present in extrinsic neurones of, for example, the vagus nerve.

Tracing peptide pathways

Although the localisation of peptide-containing cell bodies and nerve terminals is now well documented, comparatively little is known about the connecting axons because their peptide content is usually too low to detect. Similar problems with catecholamine axons were solved by transection experiments in which the pile up of transmitter on the cell body side of the lesion allowed mapping of the axon pathways¹²². Even so, a very large number of consecutive sections must be processed in order to follow long pathways, for example, from the lower brain stem to the forebrain. Anterograde and retrograde tracing techniques¹²³ helped overcome this limitation. In particular, retrograde peroxidase tracing^{124,125} combined with immunochemical 'staining' with antiserum to tyrosine hydroxylase¹²⁶ has enabled the projection of dopaminergic neurones to be mapped. More recently we have combined retrograde fluorescent dye tracing¹²⁷ with peptide immunohistochemistry¹²⁸ to map, for example, an

enkephalin-immunoreactive pathway from the lower medulla oblongata to the spinal cord⁸⁴.

Coexistence of peptides and 'classical' transmitters

The coexistence of peptides and amines is well known in endocrine cells, particularly in the gastro-intestinal tract^{19,129-131}. According to Pearse, these cells belong to the APUD system, the cells of which are "neuroendocrine-programmed cells originating from the ectoblast"^{19,132,133}. As neurones have the same embryonic origin it was postulated that they also may contain both a peptide and an amine. The fact that several examples have been observed in a relatively short time (Table 1) may indicate the generality of this situation^{18,71,83,103,106,134-144}. Further examples may be found when new techniques or new markers for other types of neurones have been developed. If so the apparent wealth of 'new' peripheral (and central) peptide neurones may, in fact, only reflect 'old' systems, which in addition to their classical transmitter contain a peptide. Perhaps it will turn out that there are no neurones that contain 'only' peptides.

The possible occurrence of two transmitters in the same nerve terminals raises the question of their subcellular storage sites (Fig. 5). In most types of nerve endings, small (diameter about 500 Å) and large (diameter about 1,000 Å) granular vesicles can be distinguished. Ultrastructural immunocytochemical studies indicate that peptides are usually present in the large vesicles⁵². No ultrastructural immunocytochemical studies have been performed on nerve endings identified and characterised as containing both a peptide and an amine (or ACh). It may, however, be speculated that, as monoamines seem to be present both in small and large vesicles^{145,146}, peptides and amines may coexist in the large vesicles, whereas the small ones may contain only the amine¹⁴⁷. A differential subcellular storage compartment is, however, suggested by the fact that even very high doses of reserpine, which almost completely deplete the monoamine stores, do not seem to affect substance P levels^{83,148}.

It has generally been assumed that one neurone produces and releases only one transmitter, a concept often referred to as Dale's principle^{149,150}. It seems, therefore, important to understand the possible functional significance of two putative transmitters in one neurone. Note that coexistence does not follow a simple pattern. For example, substance P and gastrin/CCK is present only in a small proportion of the 5-HT and dopamine neurones, respectively, originally described by Dahlström and Fuxe¹⁵¹. Similarly, we have observed many more substance P-immunoreactive cell groups (about 30)²⁹ than those containing both substance P and 5-HT. In no case do all of the neurones that contain a particular classical neurotransmitter also contain the same peptide and vice versa. Several explanations seem possible, but an attractive hypothesis is that each type of neurone, defined by the classical neurotransmitter that it

contains, is subdivided into groups characterised by the peptide they contain. We and many others have, in the analysis of the monoamine neurones, previously been struck by their apparent widespread distribution and homogeneity. But perhaps there is really a heterogeneity in which the specific peptides or each subgroup confers the ability to convey differentiated messages.

The best neurones so far available for a functional analysis seem to be those that contain VIP-like immunoreactivity, whilst being rich in acetylcholinesterase (AChE)^{143,144}. Such neurones were first observed in lumbosacral, sympathetic ganglia¹⁴³, which contain one of the best defined cholinergic (AChE-rich and choline acetylase-containing) neurone populations and are assumed to be involved in the regulation of sweat secretion¹⁵²⁻¹⁵⁴. More recent evidence, however, suggests that VIP in cholinergic neurones may be a general characteristic of secretomotor neurones¹⁴⁴. In Fig. 6 a hypothesis for the physiological significance of such neurones is presented. It is generally accepted that ACh produces secretion by an action on the secretory cells (directly and/or indirectly via myoepithelial cells) and that this effect is atropine-sensitive^{152,155}. The concomitant vasodilation, which occurs on stimulation of the postganglionic nerves, on the other hand, is atropine-resistant¹⁵⁵⁻¹⁵⁷. On the basis of studies on colon Fahrenkrug *et al.*¹⁵⁸ have suggested that VIP may be the mediator of atropine-resistant vasodilation. It is now postulated that these two effects—the secretion and vasodilation in exocrine glands—are induced by ACh and VIP, respectively, released from the same nerve terminals to act synergistically^{143,144}. In this particular situation the two putative transmitters would thus act on receptors located on two separate cell types. Clearly, in other systems different mechanisms may operate. There is, for example, evidence that substance P may block cholinergic receptors¹⁵⁹⁻¹⁶¹. In addition, preliminary studies indicate an interaction between 5-HT and substance P at the same receptor in the spinal cord¹⁶², which would agree with the existence of nerve terminals in the spinal cord containing both these compounds⁸³.

Just as the APUD concept has been of importance for our understanding of pathological processes, for example endocrine tumours (so called apudomas) in the gut¹⁶³, so may the coexistence of transmitters be to our understanding of neurological diseases and their treatment. Of particular interest in this respect is the occurrence of a CCK-like peptide in a subpopulation of dopamine neurones in rat and man^{18,142}. In the rat these cells are located mainly in the most medial parts of the zona compacta of the substantia nigra (A9 group)¹⁵¹ and in the ventral tegmental area (A10 group)¹⁵¹ and are known to project mainly to limbic areas in the forebrain¹⁶⁴. In agreement, CCK-immunoreactive (and dopamine-containing) nerve endings are found, for example, in the nucleus accumbens and the tuberculum olfactorium¹⁴².

The occurrence of a peptide in a population of dopamine neurones is interesting in view of our extensive knowledge of the functional role of these dopamine systems. In particular, the mesolimbic dopamine systems have been associated with higher mental functions and, according to the so called dopamine hypothesis, disturbances in this system may represent one component in the pathogenesis of schizophrenia¹⁶⁵. If a CCK-like peptide is released together with dopamine, the peptide could also be involved in the aetiology and symptomatology of schizophrenia. It has recently been demonstrated that CCK fragments can inhibit dopamine release in the nucleus accumbens-tuberculum olfactorium region¹⁶⁶. Thus, the peptide released together with the 'main' transmitter dopamine may be part of an inhibitory feedback system modulating dopamine release via action on autoreceptors. We have speculated¹⁶⁶ that an imbalance between peptide and amine, in fact, could be an aetiological factor for schizophrenia, whereby a loss or decrease in peptide would lead to an 'overactive' dopamine system¹⁶⁵.

Finally, the coexistence of putative peptides and biogenic amine transmitters raises questions about substitution therapy. The belief that some mental and neurological disorders are due to degeneration of transmitter-characterised systems has

Fig. 5 Schematic illustration of four alternatives for possible storage sites of an amine (5-HT) and a peptide (substance P) coexisting in a nerve ending (From ref. 80).

Fig. 6 Schematic illustration of our working hypothesis on the sympathetic innervation of sweat glands. Acetylcholine (thick arrow) and VIP (thin arrow) are released from the same nerve endings. Whereas VIP mainly causes vasodilation by relaxing smooth muscle cells (SM) around blood vessels (1), ACh mainly causes secretion by direct stimulation of secretory cells (2) or indirectly through myoepithelial cells (ME) (3) (from ref. 143).

formed the basis of therapy by administration of the lost transmitter (or its precursor). The best example is Parkinson's disease which is now, due to the pioneering work of Carlsson, Cotzias and Hornykiewicz and others¹⁶⁷, known to be due to degeneration of dopamine systems in the basal ganglia and which can be treated by peripheral administration of L-dopa, the precursor of dopamine. It is obvious that if a neurone releases two transmitters, substitution should, at least in certain conditions, consequently occur with both substances. It may therefore be that future substitution therapy will have to consider administration of two or more components. This argument is, however, not valid if the peptide acts on a presynaptic receptor, as discussed above for the limbic dopamine/CCK neurones. For this particular system other aspects must be considered in relation to drug therapy. Schizophrenia is routinely treated with neuroleptics assumed to exert their beneficial effects via blockade of dopamine receptors¹⁶⁸. It may be that 'dopamine overactivity' can be reduced also by administration of CCK fragments or drugs acting on the hypothetical CCK receptors on dopamine nerve endings¹⁶⁶.

Conclusion

Although our understanding of the functional role of peptides is still incomplete, interesting discoveries have been made. For example, the posterior pituitary hormones seem to be involved in memory processes¹⁶⁹, central endorphins are important in

pain mechanisms¹⁷⁰, substance P in primary sensory neurones may be involved in processing of pain and in axon reflexes causing vasodilation in skin⁹⁶, CCK octapeptide causes satiety¹⁷¹, angiotension II injected intracerebrally stimulates drinking and increases blood pressure^{172,173} and LHRH increases sexual behaviour¹⁷⁴. The effects mentioned above represent a narrow selection of the work going on in the field of neuropeptide physiology but illustrate the wide variety of functions in which peptides may be involved. In parallel work our knowledge of the electrophysiological characteristics of peptide neurones is rapidly advancing¹⁷⁵⁻¹⁷⁷.

Finally, peptides have been identified in the brain, spinal cord and periphery. Several of these peptides were already known as peripheral hormones. Thus, one and the same peptide, can be present in intestinal endocrine cells, gut neurones, sensory neurones of various types and in a large number of central systems. This may be a way of 'economising' on genetic material. At present the identification of the intraneuronal peptides rests mainly on immunological techniques. But new techniques mean that it will soon be possible to chemically characterise very small samples of peptides. The 'peptide maps' so far published may then have to be revised. Sometimes, or maybe even always, these peptides are found in neurones which also contain one of the classical transmitters, such as a catecholamine, 5-HT or ACh.

There is experimental evidence that at least some of these peptides, for example substance P, act as neurotransmitters. However, comparatively little is known about their exact physiological role. This is partly due to a lack of drugs which can influence peptide induced events at synapses. The wealth of such drugs discovered and developed for studies of monoaminergic mechanisms has been an important reason for the rapid advancement of our understanding of the roles of dopamine, noradrenaline and 5-HT neurones in the brain in normal and pathological conditions^{178,179}. Whilst awaiting the development of equivalent drugs for peptides, some results can be expected from the use of antisera which block peptide-induced effects^{144,180}.

ARTICLES

Diffusion of light hydrocarbons through near-surface rocks

D. Leythaeuser, R. G. Schaefer & A. Yüklér

Institute for Petroleum and Organic Geochemistry (ICH-5), Kernforschungsanlage Jülich, PO Box 1913, D-5170 Jülich, FRG

The sharply decreasing concentrations for individual light hydrocarbons over the near-surface intervals from several organic matter-bearing shale outcrops indicate that diffusion towards the lithosphere/atmosphere interface is a continuous process. Diffusion coefficients calculated are between 10^{-6} and 10^{-8} $\text{cm}^2 \text{s}^{-1}$ for propane to heptane-range hydrocarbons.

ORGANIC matter in sedimentary rocks which occurs primarily in a solid finely disseminated condition¹ is often very inhomogeneously distributed by interbedded rich and lean strata. Molecular diffusion of light hydrocarbons, generated by burial and temperature increase, through water saturated rock pore spaces should, therefore, be widespread in those sedimentary sequences. Diffusion of propane to heptane-range hydrocarbons through the caprock of a reservoir oil accumulation has been observed². However, except for experimental measurements³ no diffusion rate data are available for light hydrocarbons through rocks in natural conditions; this is partially due to inadequate subsurface sampling. Diffusion of light hydrocarbons is also most likely to occur at the exposed surface of an organic matter-rich shale which, before uplift, had been buried deep enough for hydrocarbon generation. Diffusion processes should be active within the near-surface interval along concentration gradients towards the interface between lithosphere and atmosphere.

Evidence is presented here that light hydrocarbons continuously migrate by molecular diffusion through near-surface intervals of source bed-type shales and ultimately escape into the atmosphere. A mathematical model is then used to calculate diffusion coefficients for individual normal and branched alkanes in the molecular range C_2 – C_7 . This, to our knowledge, is the first case where absolute rates of diffusion of these light hydrocarbons through rocks were determined in natural conditions. The geochemical significance of these diffusion coefficients is shown by the amount of petrogenic hydrocarbons which return into the global carbon cycle by continuous slow degassing of the lithosphere.

Samples and methods

For this study 38 samples were taken at close intervals from cores of three shallow boreholes (6.70, 8.10 and 10.0 m deep) drilled vertically into outcrops of source bed-type shales. Each core hole was spudded in fresh outcrop, that is any soil, unconsolidated overburden and weathering debris were removed. Core holes B and E were drilled into outcrops of dark grey, silty shales of Upper Cretaceous Campanian/Maastrichtian-age at Itivdle and Niaqorssuaq on Nûgssuaq Peninsula, West Greenland. Core hole H penetrated dark grey, calcareous shales of Lower Jurassic Pliensbachian age at an abandoned quarry near Jöllenbeck, North-west Germany. Well consolidated shales of low porosity and permeability which showed no visible traces of weathering alterations of the minerals were found throughout the total length of each core except for a thin, nearly horizontal fracture at 7.3 m depth location H. For a 5-cm thick interval on either side of this fracture the walls of which were stained by iron oxides, the shale showed a pronounced colour change to light grey. A sample was analysed both from this zone and the unweathered dark shale 10 cm below. An outcrop sample from 0.3 m depth was also obtained at each drill site by normal digging. All samples were sealed immediately in

gas-tight tin cans on core retrieval and were stored frozen in the laboratory.

Low molecular weight hydrocarbons were analysed by hydrogen stripping combined with capillary gas chromatography⁴. A glass tube containing a freshly crushed rock sample is placed between the capillary column and the carrier gas supply. Then the sample is stripped by a measured volume of the carrier gas (hydrogen) at ambient temperature. After intermediate trapping the volatile compounds are transported by the carrier gas into the chromatograph by splitless introduction. Detailed compositional information including identification of ~32 individual hydrocarbons in the molecular range C_2 – C_8 is obtained from a 1-g sample. This new method is very sensitive, for example, the lowest detectable quantity for *n*-butane is $10^{-9}\%$ w/w sediment. The kerogen quality was analysed by a pyrolysis technique⁵.

All three shale units contain significant concentrations of organic carbon (2.7, 6.1 and 1.0% mean for core holes B, E and H respectively) and exhibit a narrow range of variation around the mean. Similarly, the kerogen in samples of all three sites is uniformly deficient in hydrogen indicating a type III quality⁶. Mean vitrinite reflectance values of 1.30, 0.98 and 1.74% for sites B, E and H, respectively, indicate that these shale units had adequate subsurface temperatures for hydrocarbon generation. The main difference between these core holes concerns the physical state of the pore water. For sites B and E, West Greenland, the presence of permafrost and thus ice filling the rock pore space can be inferred from their high latitude geographic location.

Fig. 1 Depletion ratio for selected light alkanes across near-surface interval of Campanian/Maastrichtian shale outcrop at core hole E, Niaqorssuaq, Nûgssuaq Peninsula, West Greenland. Depletion ratio is defined as the ratio of the sample concentration at 0.3 m to the mean concentration of all samples below 3 m depth.

Fig. 2 Depth-plots of *n*-alkane concentrations (ng per g C_{org}) for core hole H, Pliensbachian shale, Jöllenbeck, North-west Germany. Note anomalous values for two samples close to major fracture at 7.3 m depth.

Distribution of light hydrocarbons in near-surface strata

Characteristic depth trends of individual light hydrocarbon (C_2 – C_8) concentrations in the Campanian/Maastrichtian age shales from West Greenland (core holes B and E) suggested that upward diffusion of ethane to pentane-range hydrocarbons was an active process within the near-surface 3-m interval. In particular, regular trends of sharply decreasing concentrations approaching the outcrop surface were recognised indicating a near-surface depletion zone. Details have been published elsewhere⁷. Figure 1 summarises the principal conclusions using core hole E as an example. Below a depth of 3 m a nearly constant concentration was observed for most hydrocarbons. The mean of all samples analysed from below that depth was considered to be the original generated concentration for this shale and is, therefore, assigned a value of unity in Fig. 1. To illustrate the degree of depletion of the sample closest to the outcrop surface, the concentration ratio 'outcrop sample/mean subsurface samples' is termed 'depletion ratio' and shown on the horizontal axis of Fig. 1. The outcrop sample of this shale is most drastically depleted in propane amounting to a 99.8% loss of the original concentration. The diffusive loss decreases drastically with increasing molecular size and also seems (except for ethane) to be controlled by molecular geometry. For example, the *n*-butane diffusive loss is 85.6% compared with 38.9% for *n*-pentane. Diffusion rates of each branched alkane are generally greater than that of the straight-chain isomer. Concentrations of *n*-hexane and *n*-heptane remain nearly constant with depth indicating no, or insignificant, diffusive loss.

Permafrost in West Greenland means that the physical conditions for light hydrocarbon diffusion through near-surface strata are different from those in North-west Germany, where the pore filling is liquid water. Figure 2 shows for core hole H, North-west Germany concentrations of *n*-alkanes ethane to heptane as a function of depth. With respect to the type and magnitude of the concentration changes, the molecular range can clearly be subdivided: for ethane to *n*-butane, comparatively small-scale concentration changes occur (most samples between 20 and 100 ng per g C_{org}), and seem to be independent of the distance from the outcrop surface. However, concentrations of *n*-hexane and *n*-heptane decrease sharply towards the exposure

surface and within the near-surface 5-m interval. The concentration depth pattern of *n*-pentane is between these two hydrocarbon groups. Only samples from depths of 7.3 and 7.4 m are exceptional and will be discussed separately.

For concentrations of *n*-hexane and *n*-heptane two depth intervals can be differentiated in core hole H: below a depth of ~5 m concentrations remain high and vary in a random fashion with depth, whereas in the shallow portion above they decrease continuously and by several orders of magnitude towards the outcrop surface. For example, most samples below 5 m depth have *n*-heptane concentrations between 15,000 and 30,000 ng per g C_{org} , whereas the sample from 0.3 m depth has only 20 ng per g C_{org} . As the molecular size increases this concentration decrease towards the outcrop surface covers a progressively greater range. For *n*-pentane it is <1, and it reaches ~2.5 orders of magnitude for *n*-heptane. Compared with these drastic concentration changes, those for ethane, propane and *n*-butane are minor.

This sharp decrease in concentration for *n*-pentane to *n*-heptane is interpreted to reflect an ~5-m thick near-surface interval where this shale has lost part of its original light hydrocarbon content into the atmosphere. An alternative explanation of an *in situ* origin of these depth concentration trends assuming different generation rates for these light hydrocarbons in the shallower than in the deeper portion of this core, can be dismissed. Concentration changes of this magnitude and over such short intervals could only result from a major change in hydrogen content of the kerogen^{2,7}. However, as discussed above, kerogen type is uniformly deficient in hydrogen

Fig. 3 Computed (broken line) and measured concentration-depth trends for selected *n*-alkanes from core hole E, Campanian/Maastrichtian shale, Niaqorssuaq, Nûgssuaq Peninsula, West Greenland. Initial concentrations C_0 used for calculation of diffusion coefficients for ethane and *n*-butane (3.1 ng per g and 165.0 ng per g respectively) are indicated by arrows.

throughout core hole H. Furthermore, a change in kerogen-type would also have to be reflected in the ethane to butane concentrations.

The rate of light hydrocarbon depletion in the shallow 5-m interval increases with molecular size producing pronounced compositional fractionation. This suggests that diffusion is the mechanism by which *n*-pentane, *n*-hexane and *n*-heptane have escaped from the near-surface 5-m interval of this shale. However, the compound separation effects in the Pliensbachian shale of core hole H are with respect to their relationship with molecular size, opposite to what would be expected from simple diffusion through porous media. The degree of depletion in the near-surface interval should be most severe for the gases and decrease with molecular size. The lack of a measurable concentration gradient for ethane, propane and *n*-butane in this shale is interpreted as an indication that only the uppermost portion of a depletion zone was penetrated, that is, the depth was not reached at which this shale has kept its original concentration for these relatively mobile hydrocarbons. The relative abundance and type of distribution of the analysed *n*-alkanes support this conclusion. A distribution envelope of continuously increasing concentrations with increasing carbon number is the opposite of what is known for a high-mature type III kerogen shale like this Pliensbachian shale². Diffusion rates seem to be strongly controlled by molecular size, that is, the shale is depleted in ethane, propane and butane to a much greater depth than for *n*-hexane and *n*-heptane.

Finally, light hydrocarbon concentrations of samples from depths of 7.3 and 7.4 m, shown in Fig. 2, deviate significantly from those of adjacent samples above and below. Both samples tend to be enriched in ethane, propane and *n*-butane, whereas they are depleted in the longer-chain *n*-alkanes. This is interpreted as reflecting the proximity of these samples to an open fracture which was visible in the core at a depth of 7.3 m. This fracture is probably in contact with the atmosphere either directly or through an interconnected fracture system. Down dip and at greater depth, ethane, propane and butane predominantly diffuse from the adjacent shale into the fracture. This hydrocarbon mixture moves upwards along the fracture, probably by a mechanism other than pure diffusion. From this gas-charged fracture ethane, propane and butane have diffused into the immediately adjacent portion of the shale causing the enrichment. The hydrocarbon mixture in the fracture lacks *n*-pentane, *n*-hexane and *n*-heptane compared with the adjacent portions of the shale. Hence those hydrocarbons diffuse towards the fracture resulting in a narrow shale interval parallel to the fracture, which is locally depleted in hexane and heptane.

Quantitative determination of diffusion coefficients

The above observations led us to calculate the absolute values of diffusion coefficients using Fick's law,

$$D \frac{\partial^2 C(z, t)}{\partial z^2} = \frac{\partial C(z, t)}{\partial t} \quad (1)$$

where $C(z, t)$ = concentration of hydrocarbons as a function of depth and time, ng hydrocarbon per g of rock; D = diffusion coefficient, $\text{cm}^2 \text{s}^{-1}$; t = time, s; z = depth, cm.

We assume that the shale unit has, at greater depth, a constant concentration, C_0 , as the initial condition

$$C = C_0 \quad \text{at} \quad \infty \geq z > 0 \quad t = 0$$

The concentration is zero at the outcrop surface, and at an infinite depth the concentration is equal to C_0 for the boundary conditions:

$$C = 0 \quad \text{at} \quad z = 0, \quad t \geq 0$$

$$C = C_0 \quad \text{at} \quad z \rightarrow \infty, \quad t \geq 0$$

Solving the diffusion equation with the above initial and boundary conditions⁸,

$$C(z, t) = C_0 \operatorname{erf} \frac{z}{2(Dt)^{1/2}} \quad (2)$$

The initial concentrations, C_0 , are determined for each *n*-alkane by calculating arithmetic or geometric means of the measured concentrations below the above defined near-surface depletion zones. Concentration values are calculated at 25-cm intervals. $D \cdot t$ is the only unknown required in the calculation of $C(z, t)$ which should correspond with the measured concentration. In mathematical terms, we try to solve an inverse problem by which one can determine the correct parameter of a system. Two techniques were used to optimise $D \cdot t$ —the least-square method, and the comparison of the areas formed between the straight lines joining the measured concentration values and the curve calculated with a certain $D \cdot t$ value. The best value of $D \cdot t$ is found with iteration that minimised the error between

Fig. 4 Calculated cumulative mass of propane and *n*-pentane escaping as a function of time into the atmosphere from a 100 km² outcrop surface of Campanian/Maastrichtian shale on Nûgssuaq Peninsula, West Greenland.

the calculated and measured concentrations. The concentration curve found solving equation (1) is convex.

Using this model, the variation of the light hydrocarbon concentrations with depth could be calculated only for core holes B and E from West Greenland. In both cases the initial concentration C_0 can be determined with reasonable accuracy. The data of core hole H are not suitable for modelling because the diffusion front moved below the depth which was reached by the drill. Once the optimum value of $D \cdot t$ is determined, the absolute value of D is calculated by dividing $D \cdot t$ by the time available for diffusion. The initiation of diffusion for light hydrocarbons is defined here as the time when the present surface of the Earth was established at the sampling locations in the course of uplift and erosion. Although there are no direct means to measure this time exactly, the special geological and geographical conditions of West Greenland enable one to make a reasonably accurate estimate. Present topography results from isostatic uplifting and subsequent erosion following retreat of the thick ice cap which once covered coastal West Greenland. This retreat is dated at 6,000 yr BP (ref. 9), which represents a maximum value for time t to solve equation (2).

As core holes B and E were drilled into shales of the same age and the concentration-depth trends were similar, only the model results for core hole E are discussed here in detail. The concentration curves are calculated from equation (2) with optimised $D \cdot t$ values as described above and plotted together with the measured concentrations for two selected n -alkanes (Fig. 3). The similarity between the convex shape of the calculated concentration curve and the general trend of the measured concentrations strongly supports our observations that the concentration depth-trends of the n -alkanes studied is indeed mainly governed by diffusion.

It was possible to calculate $D \cdot t$ values for n - and iso-butaness and -pentanes, n -hexane and n -heptane in core hole B, and for ethane, propane, n - and iso-butaness and -pentanes in core hole E. Diffusion coefficients calculated (Table 1), vary from 10^{-6} to $10^{-8} \text{ cm}^2 \text{ s}^{-1}$. As Table 1 also shows, they compare favourably with data reported for methane although measured in recent sediments¹⁰. The calculated diffusion coefficients in core holes B and E show a strong dependence on molecular size and geometry: they decrease rapidly with increasing carbon number, except for ethane. The branched alkanes have higher diffusion coefficients than their normal homologues. Comparison of the calculated absolute diffusion coefficients for n - and iso-butaness and -pentanes in core holes B and E shows a good match (for example, for the normal alkanes 3.5×10^{-7} and $1.4 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ in B compared with 3.2×10^{-7} and $1.1 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$ in E) which also indicates that the model represents a good first approximation.

Geochemical significance

Based on these absolute diffusion rates several geological processes involving hydrocarbon diffusion can now be quantified. The contribution of diffusion to primary migration of hydrocarbons, thought to involve a combination of different transport mechanisms¹¹, can now be estimated. Within the shale source beds hydrocarbons diffuse over short distances along concentration gradients towards the nearest fracture, vug or silt layer¹. Geochemical surface prospecting is based on the concept of light hydrocarbons diffusing from reservoir accumulations in the subsurface towards the Earth's surface¹². However, a reliable geochemical interpretation of such data should take into account the compositional fractionation effects documented here. Details of these geological applications will be published elsewhere.

The rate at which petrogenic hydrocarbons escape by continuous slow degassing from the lithosphere is of great interest when establishing the global carbon cycle in general and the atmospheric carbon balance in particular¹³⁻¹⁵. Based on the diffusion coefficients, the cumulative mass of propane and n -pentane escaping into the atmosphere as a function of time from

a 100-km² outcrop surface of the Campanian/Maastrichtian shale in West Greenland is calculated and shown in Fig. 4. During the initial periods, as the shale is uplifted and exposed to the surface of the Earth, high amounts of hydrocarbons enter the atmosphere per unit time, (for example, 1.1×10^5 and $1.0 \times 10^4 \text{ kg}$ in the first year for propane and n -pentane respectively), decreasing exponentially with time. However, this calculation is based on the simplified assumption that the exposure surface remains constant with time, that is that there is no continued advance of the diffusion front with progressing erosion.

Conclusions

Rocks from the near-surface intervals of three shallow core holes drilled in source bed-type shales exhibit a pronounced depletion in concentration of certain light hydrocarbons (C_2 - C_7) towards the outcrop surface. A major difference is observed in the type and depth of this depletion zone between the three cases examined. In two shale outcrops in West Greenland a depletion zone can only be recognised for ethane through pentane-range hydrocarbons and to a depth of 3 m. In North-west Germany the shale is depleted in ethane to butane-range hydrocarbons to an unknown depth which is $>10 \text{ m}$. However, for pentane to heptane-range hydrocarbons the depletion zone extends only to a depth of 5 m. This difference between West Greenland and North-west Germany reflects the influence of permafrost, that is, ice plugging the pore space retards depletion processes.

These near-surface depletion zones are explained as a result of molecular diffusion of light hydrocarbons through the water saturated pore space of the shales along concentration gradients towards the Earth surface. However, several physical factors, which have probably influenced the upward diffusion of light hydrocarbons through the shale section studied, have been neglected in the present stage of our model: adsorption of light hydrocarbons on mineral surfaces, or the inhomogeneity of the porous media, that is subtle changes with depth in clay mineralogy, porosity and permeability.

The concentration-depth trends computed by the mathematical model based on Fick's law closely match those measured for both core holes in West Greenland. An assumption of time available for diffusion in these cases makes it possible to determine absolute diffusion rates of hydrocarbons through a column of rocks in natural conditions. These diffusion coefficients vary between 10^{-6} and $10^{-8} \text{ cm}^2 \text{ s}^{-1}$ for ethane to heptane-range hydrocarbons and decrease sharply with molecular size.

Financial support by the German Federal Ministry of Research and Technology (BMFT) grant ET 3070 B is acknowledged. We thank Dr E. J. Schiener for making possible the collection of sample sets from West Greenland; Dr M. Büchner for stratigraphic information on core hole H; also Dr K. Schroeder, for helpful discussions of the quantification of the diffusion process; Dr M. Whiticar, for his corrections; Dr P. Flekken for the vitrinite reflectance data; and Misses Beckers, Frauenrath and Jacobs, and Messrs Benders, Disko, Schmidl and Weiner for technical assistance.

A DNA cloning system for interspecies gene transfer in antibiotic-producing *Streptomyces*

Mervyn Bibb, Janet L. Schottel & Stanley N. Cohen

Departments of Genetics and Medicine, Stanford University School of Medicine, Stanford, California 94305

Selectable plasmid vectors that contain a gene encoding resistance to the antibiotic methylenomycin A and that are suitable for the cloning of endonuclease-generated DNA fragments in *Streptomyces* species have been constructed and characterised.

STREPTOMYCES are Gram-positive mycelial bacteria which undergo a complex process of morphological differentiation. Because more than 60% of known antibiotics are produced by *Streptomyces* species, including many products of widespread use in human and veterinary medicine and in agriculture, these organisms hold a position of considerable medical and biological importance¹. The development of a DNA cloning system for *Streptomyces* would greatly facilitate the detailed genetic analysis of their antibiotic production pathways and of the molecular mechanisms involved in their differentiation. Furthermore, DNA cloning could produce new combinations of DNA sequences from genetically diverse organisms and perhaps result in new types and increased yields of antibiotics synthesised by these actinomycetes.

Although the process of gene exchange mediated by conjugation within actinomycetes is apparently widespread², the transfer of genetic material between individuals by such sexual means is predominantly restricted to members of the same or closely related species. The recent development of a method for protoplast fusion in *Streptomyces*^{3,4} represents a significant advance in the ability to use genetic recombination as a practical tool in the field of strain improvement; however, the production of recombinants in fused protoplasts by 'homologous recombination' is limited by the extent of DNA sequence similarity. DNA cloning methods potentially permit the insertion of a DNA sequence of any origin into a particular host strain, provided that a suitable vector system is available to propagate the cloned DNA and a means of introducing the recombinant DNA molecule into the host organism exists.

An earlier report⁵ has described a plasmid transformation system that results in the high frequency uptake of covalently closed circular (CCC) DNA by *Streptomyces* in the presence of polyethylene glycol, and allows the visual detection of transformants, after protoplast regeneration, that occur at a frequency of less than 10^{-5} . In optimal conditions, at least 20% of the regenerated protoplasts of *Streptomyces coelicolor* or *Streptomyces parvulus* were transformed with the *S. coelicolor*

plasmid SCP2* and 10^6 transformants per μg of plasmid DNA were obtained; similar results were obtained with *Streptomyces lividans* protoplasts transformed with SLP1 plasmid DNA.

The availability of an efficient system for introducing plasmid DNA into *Streptomyces* species provides a basic tool for DNA cloning in this genus. We report here the development of a *Streptomyces* cloning system using derivatives of two unrelated plasmids, SCP2* and SLP1.2.

Plasmids used for construction of cloning vectors in *Streptomyces*

Two groups of plasmids were potentially suitable for the construction of cloning vectors for *Streptomyces*:

- (1) SCP(2) and its high fertility variant, SCP2*, were first isolated from *S. coelicolor* A3(2), and both plasmids have been subjected to genetic and physical analyses⁶⁻⁸. Strains containing either of the plasmids elicit a phenomenon termed lethal zygotis when grown in contact with an SCP2⁻ culture of the same species^{6,8}. Lethal zygotis is associated with plasmid transfer and results in the retardation of the development of the SCP2⁻ culture. This phenotype proved useful in the development of a plasmid transformation system for *Streptomyces* and has facilitated the detection of low-frequency interspecific transfer of SCP2* from *S. coelicolor* to *S. lividans* and *S. parvulus*. Other *Streptomyces* plasmids have subsequently been shown to elicit and confer resistance to lethal zygotis, including SCP1 from *S. coelicolor* and the SLP1 series of plasmids from *S. lividans*. This property seems to be a fairly common phenotype among *Streptomyces* plasmids and may prove useful in identifying additional plasmids that are otherwise phenotypically cryptic. SCP2* and SCP2 have a molecular length of 31 kilobases, are present in the mycelium at about one copy per genome and have identical restriction endonuclease cleavage maps (Fig. 1) for all enzymes used.
- (2) The SLP1 series of plasmids was isolated from *S. lividans*⁹. Six different plasmid species SLP1.1-6, of molecular length

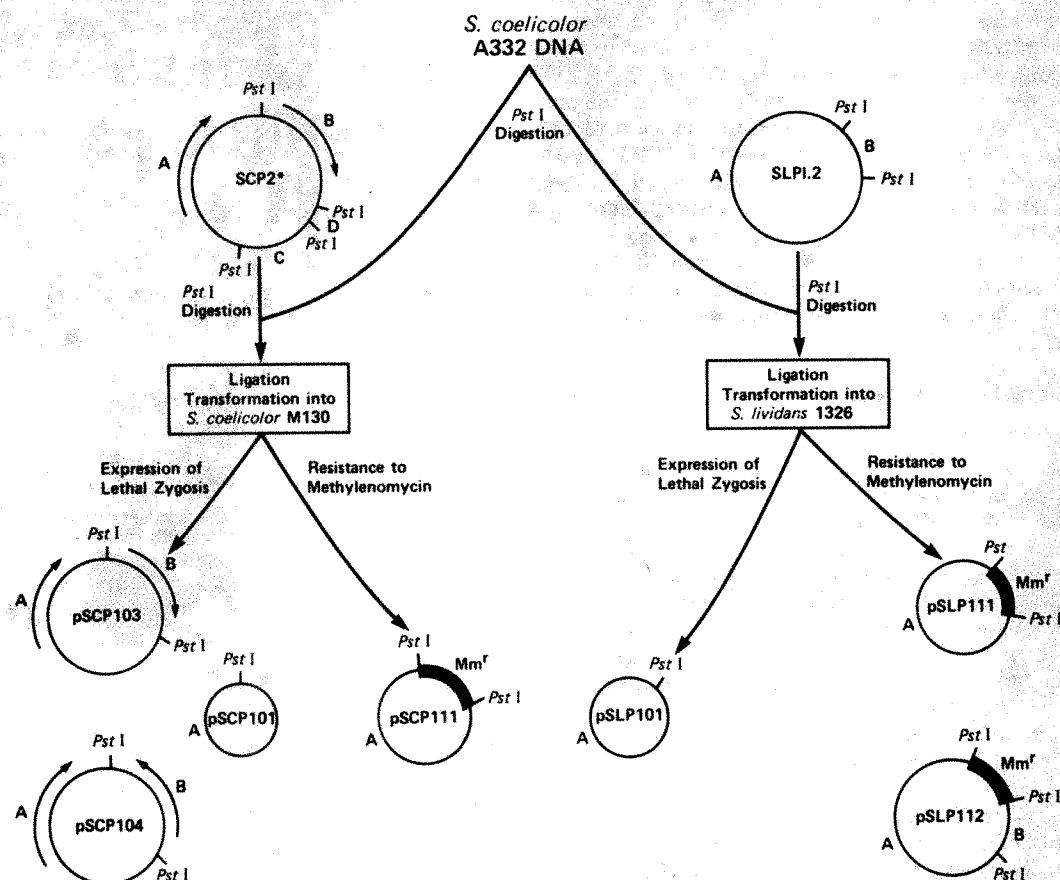

Fig. 1 Restriction endonuclease cleavage maps of the SCP2* and SLP1.2 plasmids. Distances are shown in kilobase (kb) pairs. The maps were derived from single, double and partial digests of SCP2* or SLP1.2 with the enzymes indicated. The shaded areas of each map indicate regions of the genomes which are non-essential for plasmid replication, and which include certain restriction endonuclease cleavage sites that are available for DNA insertion.

Fig. 2 Schematic outlines of the procedure used for cloning the Mm resistance gene(s) on SCP2* and SLP1.2 derived vectors. 0.5 µg of SCP2* DNA, isolated as covalently closed circular (CCC) DNA from *S. coelicolor* strain M109 and 2.5 µg of DNA isolated from *S. coelicolor* strain A332 were digested to completion with *Pst*I, mixed and ligated together at a total DNA concentration of 12 µg ml⁻¹. Similarly, 0.1 µg of SLP1.2, prepared in an identical fashion to SCP2* but from *S. lividans* M180, and 1 µg of A332 DNA were completely digested with *Pst*I, mixed and ligated together at a final concentration of 15 µg ml⁻¹. Each mixture was assayed by agarose gel electrophoresis, precipitated with ethanol, resuspended in 20 µl 10 mM Tris-HCl, pH 8, and 1 mM EDTA (TE buffer) and introduced by transformation into either 10⁷ *S. coelicolor* M130 or 2 × 10⁷ *S. lividans* 1326 protoplasts, respectively. As a control for the spontaneous occurrence of Mm^r-resistant isolates, equal numbers of protoplasts were treated with 20 µl TE buffer in an identical manner. After allowing time for protoplast regeneration and sporulation to occur⁵, spores were collected from the regeneration plates by the addition of 10 ml of sterile distilled water and gentle scraping with a wire loop, filtered through cotton wool, concentrated by centrifugation at 1,000 g for 15 min and resuspended in 0.3 ml 20% glycerol. The spore preparations were then assayed either for the presence of Mm^r clones (Fig. 3) or for expression of lethal zygosis. The remainder of the spore preparation was stored frozen at -20 °C with only slight loss of viability.

9.38–12.35 kilobases, have been isolated and shown by restriction enzyme cleavage mapping to be identical except for a single segment of the plasmid genome. As the size of the plasmid in the series increases, the length of the DNA segment comprising the variable region increases in one direction only from a fixed point. Some of the larger variants consequently acquire additional restriction endonuclease cleavage sites that are contained in DNA sequences not essential for autonomous replication. Thus, insertion of exogenous DNA fragments into these cleavage sites should not interfere with propagation of the plasmid. Particularly attractive as a potential cloning vector is SLP1.2 (12.35 kilobases), which contains a single *Bam*HI and two *Pst*I restriction sites, all within the non-essential variable region (Fig. 1). The SLP1 series of plasmids are self-transmissible and have an estimated copy number of four or five per genome (M.B., unpublished).

Only covalently closed supercoiled plasmid DNA molecules have been used in earlier transformation experiments in *Streptomyces*⁵. Preliminary experiments were therefore carried out to determine the efficiency of uptake of linear and re-ligated plasmid DNA by protoplasts in transformation conditions. SCP2* and SLP1.2 DNA were cleaved into full-length fragments with *Hind*III and *Bam*HI endonucleases, respectively, and subjected to electrophoresis on a 1% agarose gel in Tris-acetate buffer. DNA bands containing linear plasmid DNA molecules were cut out from the gel, separating these from uncleaved molecules present in the endonuclease-treated samples. Linear SCP2* DNA was purified by potassium iodide gradient centrifugation¹⁰, and the linear SLP1.2 fragment was removed from the gel slice by electroelution as described below. Treatment of linear plasmid DNA with bacteriophage T4 ligase resulted in 50% conversion to circles, as estimated by gel electrophoresis (data not shown). Ligated or unligated samples of SCP2* and SLP1.2 were then used for transformation of protoplasts of *S. coelicolor* strain M124 and *S. lividans* strain

1326, respectively, and transformants were identified by their ability to elicit lethal zygosis when placed onto a lawn of a plasmid-minus strain of the same species. Transformation frequencies in excess of 10⁵ per µg DNA were obtained for ligated DNA samples; unligated DNA gave a 10–100-fold lower transformation frequency.

Cloning of a DNA fragment determining resistance to methylenomycin A

Because neither the SCP2* nor the SLP1.2 plasmid contains a known drug-resistance gene readily usable in selection of transformants, we chose in our initial experiments to clone the gene(s) specifying resistance to the antibiotic methylenomycin A (Mm)¹¹; this would then be useful for selection purposes in subsequent cloning experiments. Methylenomycin A has antibiotic activity against a wide range of Gram-positive eubacteria and many *Streptomyces* species. Genes encoding Mm resistance as well as Mm production are present on a genetically but not physically identified plasmid, SCP1 (ref. 12). *S. coelicolor* strain A332 contains the SCP1 plasmid integrated into the chromosome and is believed to possess a single copy of the Mm resistance gene(s) per genome¹³.

The total DNA of *S. coelicolor* A332 was digested with *Pst*I endonuclease, ligated to similarly cleaved SCP2* or SLP1.2 plasmid DNA, and introduced by transformation into *S. coelicolor* or *S. lividans* protoplasts as described in Fig. 2. Spores of each strain were then tested for resistance to Mm and the ability to elicit lethal zygosis. The antibiotic produced by an SCP1-containing strain was used to select for any Mm^r clones present in a lawn of the collected transformation mixtures¹⁴.

Figure 3A illustrates the selection of Mm^r clones of *S. coelicolor*. Mm^r clones of *S. lividans* were selected in a similar way using patches of *S. lividans* SCP1⁺ strain M233 as a source of Mm. Colonies of *S. coelicolor* and *S. lividans* picked from within

the areas of inhibition of the background lawn were tested for Mm resistance and shown to be resistant to the antibiotic, in contrast to the inhibition observed for strains M130 and 1326 added, respectively, as controls to each of the plates (Fig. 3B).

When purified *S. coelicolor* Mm^r clones were replica-plated to lawns of M130 (*hisA1*, *uraA1*, *strA1*, SCP2⁻) and M110 (*hisA1*, *uraA1*, *strA1*, SCP2⁺) on supplemented R2 medium plates³, each antibiotic-resistant clone elicited lethal zygotis against M130 but not against M110, indicating the presence of an SCP2⁺-related plasmid. Similarly, the Mm^r clones of *S. lividans* also exhibited lethal zygotis characteristic of the SLP1 series of plasmids, again indicating the presence of an SLP1 derivative in these clones.

Analysis of methylenomycin-resistant plasmids

Plasmid DNA obtained from Mm^r clones of both *S. coelicolor* and *S. lividans* was isolated using caesium chloride-ethidium bromide density gradient centrifugation⁶. Gel analysis of restriction endonuclease-cleaved CCC plasmid DNA obtained from a randomly selected antibiotic-resistant clone of *S. coelicolor* indicated that it consisted of a single molecular species 18 kilobases long and contained single *Bam*HI and *Eco*RI sites. Further analysis of this plasmid species (designated pSCPIII) by endonuclease digestion and gel electrophoresis (Fig. 4) indicated that it contains the largest *Pst*I fragment of SCP2⁺ plus a novel fragment of 2.55 kilobases that presumably carries the gene(s) conferring resistance to Mm.

Similar gel analysis of the endonuclease-cleaved DNA obtained from a Mm-resistant clone of *S. lividans* revealed a plasmid species of molecular length 13.3 kilobases that also includes single cleavage sites for *Eco*RI and *Bam*HI. Additional gel analysis of this plasmid DNA species, designated pSLPIII (Fig. 4), indicated that it consists of the larger *Pst*I fragment of SLP1.2 plus a novel fragment of molecular length 2.55 kilobases. Another independently isolated Mm^r-resistant clone of *S. lividans* yielded a full-length SLP1.2-derived plasmid (pSLP112) that contained a 2.55 kilobase *Pst*I-generated fragment inserted into one of its two *Pst*I sites (Fig. 2). Hence, three independently obtained Mm^r clones all contained plasmid derivatives that included a *Pst*I-generated DNA fragment 2.55 kilobases long, suggesting that this inserted fragment included the Mm resistance gene(s). In each case the cloned *Pst*I-generated fragments lacked sites for *Bam*HI, *Eco*RI and *Hind*III.

Table 1 Stability of SCP2⁺ derivatives

Plasmid	% Loss per life cycle	
	In <i>S. coelicolor</i> strain M130	In <i>S. lividans</i> strain 1326
SCP2 ⁺	0.5 (2/420)	4 (9/224)
pSCP101	9.0 (15/168)	35 (79/224)
pSCP102	7.0 (12/168)	34 (95/280)
pSCP103	0.3 (0/336)	NT
pSCP104	0.5 (0/232)	NT
pSCP111	22.0 (50/224)	NT
	35.0 (90/254)*	NT

For all derivatives, spores were scraped from single colonies that expressed lethal zygotis when replicated onto a lawn of an SCP2⁻ strain, serially diluted and plated onto complete medium. The resulting colonies were assayed for their ability to express lethal zygotis by replication onto lawns of SCP2⁻ strains of the same species. In addition, for pSCP111, a portion of the spores from a single colony was streaked at 90° to a culture of M146 on complete medium to test for Mm resistance; this test confirmed the presence of pSCP111 in the spore that gave rise to the assayed colony. Spores from the original colony were suspended in water, serially diluted and plated onto complete medium. The resulting single colonies were then streaked against M146 to assay again for Mm resistance, which showed the continued presence of pSCP111. These plates were later replicated to lawns of M130 on supplemented R2 medium to assay for the ability of the isolates to express lethal zygotis. All Mm^r isolates expressed lethal zygotis and all Mm^s isolates did not, indicating that the loss of pSCP111 rather than DNA rearrangements resulted in a Mm-sensitive phenotype. Numbers in parentheses indicate the number of colonies not showing lethal zygotis (or for pSCP111 not showing Mm resistance) over the total number of colonies. NT, not tested.

* Loss of Mm resistance.

Fig. 3 Selection of Mm^r clones. A, 0.1-ml volumes of the collected *S. coelicolor* M130 transformation and control mixtures were spread onto complete medium agar²³ and the plates allowed to dry. Three patches of *S. coelicolor* SCP1⁺ strain M146 were applied to both plates, which were then incubated at 30 °C for 4–6 days: (1) transformation mixture resulting from the treatment of M130 protoplasts with TE buffer; (2) transformation mixture resulting from the treatment of M130 protoplasts with a ligated mixture of *Pst*I-cleaved SCP2⁺ and A332 total DNA. The presence of resistant colonies in the area of inhibition of the lawn produced by diffusion of Mm from the M146 patches is seen. B, Colonies growing in the zones of inhibition of plate A2 were streaked at right angles to a culture of the SCP1⁺ strain M146 on complete medium and incubated at 30 °C for 3–5 days. Aerial mycelium formation and sporulation of the Mm-sensitive control cultures M130 (SCP1⁻, SCP2⁻) (a), M110 (SCP1⁻, SCP2⁺) (b) and 1190 (SCP1⁻, SCP2⁺) (c) are inhibited proximal to the antibiotic produced by M146. Streaks of the clones picked from A2 and of strain M146 (d) were resistant to Mm.

To confirm that the novel fragment conferring Mm resistance did, in fact, contain the Mm^r gene(s) from the chromosomally integrated SCP1 plasmid, a labelled probe of pSCP111 was made by nick translation¹⁵ using [α -³²P]dCTP. This probe was then hybridised using the method of Southern¹⁶ (with modifications) to *Pst*I-cut total DNA that was isolated from two SCP1⁺ and two SCP1⁻ isolates of *S. coelicolor* (Fig. 5). The labelled pSCP111 DNA hybridised to only the *Pst*I-A fragment of SCP2⁺ (15.4 kilobases) and to DNA fragments of 2.55 kilobases present in the SCP1 containing strains A332 and M146. No hybridisation to DNA fragments of this size could be seen with the SCP1⁻ M130 and M110 DNA samples.

Interspecific expression of pSCP111

The ability to transfer genes among different *Streptomyces* species and to obtain phenotypic expression in the new host is of potential importance in the use of DNA cloning methods for the development of new antibiotics. To investigate whether the cloning system described above is likely to be of general use in *Streptomyces* species, we transformed derivatives of *S. lividans* and *S. parvulus* with pSCP111 and selected for Mm resistance using the method described previously. Protoplasts were prepared from cultures of *S. lividans* 1326 and *S. parvulus* 2283 and transformed with 10 ng of purified pSCP111 DNA. After protoplast regeneration, the resulting spore preparations were assayed for the presence of Mm^r clones using *S. lividans* strain M233 (SCP1⁺) and *S. coelicolor* strain M146 (SCP1⁺), respectively, as sources of Mm for the *S. lividans* and *S. parvulus* transformation mixtures. In both cases antibiotic-resistant colonies were obtained. Plasmid DNA was isolated from the *S. lividans* and *S. parvulus* Mm^r-resistant derivatives using caesium chloride-ethidium bromide density gradient centri-

Table 2 Fertility properties of SCP2* derivatives

Components of mating	Colony-forming units per ml on [†] :				Average recombination frequency [‡]	Plasmid transfer frequency (% per recipient)
	HUS (Parentals)	PAC	PACUS (Recombinants)	PCH		
M130 × M124	3.5 × 10 ⁹	1.2 × 10 ⁹	1.2 × 10 ²	20	3.9 × 10 ⁻⁸	—
M130 (SCP2*) × M124	5.0 × 10 ⁸	5.6 × 10 ⁸	2.1 × 10 ⁵	3.7 × 10 ⁶	3.7 × 10 ⁻³	100 (100/100)

						55 (74/134)‡

Matings were carried out as previously described²³. Plasmid transfer frequency was determined by patching colonies from the PAC plates on to minimal medium containing proline, arginine and cysteine and after sporulation replicating to a lawn of M130 spread on fully supplemented R2 medium. The colonies were then scored for their ability to elicit lethal zygosis.

§ Minimal medium containing some of the following supplements: histidine (H), uracil (U), streptomycin (S), proline (P), arginine (A) and cysteine (C).

† Expressed as the average of the mean recombination frequencies of each parent.

‡ The transfer frequency of pSCP111 was also determined by streaking colonies from the PAC plates at right angles to M146 on complete medium and scoring for Mm resistance. M130 = *S. coelicolor* hisA1, uraA1, strA1, SCP1⁺, SCP2⁺; M124 = *S. coelicolor* proA1, argA1, cysD18, SCP1⁺, SCP2⁺.

fugation and was indistinguishable from pSCP111 by gel analysis of *Pst*I endonuclease digests.

We also transferred pSCP111 from *S. coelicolor* to *S. lividans* and *S. parvulus* by mating, selecting for Mm^r exconjugants. We have demonstrated, therefore, that the pSCP111 vector can be introduced by transformation or conjugation into two different *Streptomyces* species, *S. lividans* and *S. parvulus*, and that transformants can in each instance be selected by expression of the Mm^r gene(s) cloned in the autonomously replicating pSCP111.

Plasmid derivatives of SCP2* and SLP1.2 and their properties

SCP2* is an autonomously replicating extrachromosomal element and so must contain at least one origin of replication. The plasmid is self-transmissible and presumably includes functions that accomplish its inter-bacterial transfer among different strains of *S. coelicolor*, although the precise mechanism of conjugation in these mycelial organisms is unknown. SCP2* expresses functions that determine the level of chromosomal recombination between two genetically distinguishable derivatives of *S. coelicolor* by a mechanism that is possibly related to the transfer properties of the plasmid. It also confers on its host cell production of and resistance to lethal zygosis⁶. The lethal zygosis phenotype depends on plasmid transfer, and resistance to lethal zygosis may be functionally analogous to the surface exclusion phenomenon expressed by the sex factor F in *Escherichia coli*¹⁷.

To localise the basic biological functions of the SCP2* plasmid, derivatives of SCP2* that contain only particular restriction fragments of the original plasmid were isolated. The *Pst*I-digested and ligated *S. coelicolor* transformation mixture used originally to select for pSCP111 (Fig. 2) was also diluted and plated on supplemented R2 medium to which sufficient spores of a culture of M130 had been added to produce a confluent lawn. After incubation at 30 °C for 3–4 days, growth-centred zones of inhibition of the background lawn characteristic of lethal zygosis were observed. Spores were picked from the centre of these zones of inhibition and streaked out to obtain single colonies which, on replication to lawns of M130 on supplemented R2, expressed lethal zygosis. In a similar manner, SCP2* digested with *Bam*HI endonuclease was ligated and introduced into M130, and single colonies which expressed lethal zygosis on lawns of M130 were purified.

Isolation of CCC DNA from these clones and subsequent restriction enzyme analysis using *Bam*HI and *Pst*I single and double digests confirmed unambiguously that the isolates all contained derivatives of SCP2* having the structures indicated

in Fig. 2. pSCP101 (15.4 kilobases) consisted of the *Pst*I-A fragment of SCP2*; pSCP102 (15.9 kilobases) consisted of the *Bam*HI-A fragment of SCP2* (not shown); pSCP103 (24.3 kilobases) consisted of the *Pst*I-A+B fragments of SCP2* orientated as in the original plasmid; and pSCP104 (24.3 kilobases) consisted of the *Pst*I-A+B fragments of SCP2* but in the opposite orientation.

As both pSCP101 and pSCP102 replicate autonomously, an origin of replication is necessarily located in the *Pst*I-A and *Bam*HI-A fragments of the parent plasmids. Similarly, as all these plasmids express lethal zygosis when replicated on to an SCP2⁺ lawn and also confer resistance to this phenotype when used as lawns themselves, the gene(s) involved in production of and resistance to lethal zygosis must also be located in this region.

Fig. 4 Gel analysis of restriction endonuclease-cleaved pSCP111 and pSLP111 plasmid derivatives. Lanes a and g, SCP2* DNA digested with *Bam*HI and *Pst*I generating fragments of 15.4, 6.8, 4.3, 2.18, 0.93 and 0.8 kilobases. All other plasmids digested with *Pst*I. b, pSLP111; c, SLP1.2; d, pSCP111; e, pSCP101 (see below); f, SCP2*. Electrophoresis was from top to bottom in 1% agarose in 40 mM Tris-acetate, pH 7.9, and 1 mM EDTA for 4 h at 50 mA.

Fig. 5 Hybridisation of ^{32}P -labelled pSCP111 DNA to isolated DNA from *S. coelicolor* Mm-resistant or sensitive isolates. Aliquots (5 μg) of DNA isolated from each of the *S. coelicolor* strains A332 (chromosomally integrated SCP1, SCP2*), M146 (SCP1*, SCP2*), M110 (SCP1*, SCP2*) and M130 (SCP1*, SCP2*) were digested with 1.5 U *Pst*I at 37 °C for 3 h and electrophoresed as indicated in Fig. 4. Samples of SCP2* and pSCP111 DNA digested with *Pst*I were also included as controls. The gel was stained in 0.5 $\mu\text{g ml}^{-1}$ ethidium bromide, photographed and then soaked twice in 250 ml 0.25 M HCl for 15 min to depurinate the DNA and so enhance transfer of the larger fragments from the gel to the nitrocellulose filter²⁴. The gel was rinsed with water and soaked twice in 250 ml 0.5 M NaOH and 1 M NaCl for 15 min to denature the DNA. The gel was washed briefly three times with 200 ml water and then neutralised by soaking it for 20 min in 200 ml 3 M NaCl and 0.5 M Tris-HCl, pH 7.5. DNA was then transferred from the gel to the nitrocellulose filter soaked with $20\times\text{SSC}$, pH 6.5 ($1\times\text{SSC} = 0.3\text{ M NaCl}$, 0.03 M sodium citrate); after 5 h of contact between filter and gel, no DNA could be detected in the gel on staining with ethidium bromide. The nitrocellulose filter was baked at 80 °C in a vacuum oven for 2 h and then prehybridised at 52 °C in the presence of 50% formamide, $6\times\text{SSC}$, pH 6.5, 25 mM sodium phosphate, pH 6.5, 0.1% sodium pyrophosphate, 10 $\mu\text{g ml}^{-1}$ boiled calf thymus DNA and 1% glycine for 12 h. 0.5 μg pSCP111 DNA was incubated at 15 °C for 2.5 h in the presence of 100 μCi [α - ^{32}P]dCTP (12.5 μM), 12.5 μM each of dATP, dGTP, dTTP, 1 $\mu\text{g ml}^{-1}$ pretreated DNase and 0.1 U μl^{-1} DNA polymerase (Boehringer-Mannheim) in 50 mM Tris-HCl, pH 7.8, 5 mM MgCl_2 , 50 mg ml^{-1} bovine serum albumin and 10 mM 2-mercaptoethanol in a total volume of 20 μl . The mixture was extracted with phenol and passed over a Sephadex G-50 fine column in 20 mM Tris-HCl, pH 8, 50 mM NaCl and 1 mM EDTA to remove unincorporated label. The resulting probe had a specific activity of 1.8×10^8 c.p.m. per μg . The prehybridised nitrocellulose filter was then hybridised to 10^7 c.p.m. of the radioactively labelled pSCP111 probe, previously denatured by heating to 108 °C for 20 min in a saturated NaCl bath. Hybridisation conditions were similar to prehybridisation conditions except that $5\times\text{SSC}$ was used and calf thymus DNA and glycine were absent. Incubation was at 52 °C for 24 h in a total volume of 1.2 ml in a sealed polyethylene bag. The filter was then rinsed twice with 50 ml of hybridisation solution, incubated three times in 50 ml of the same solution at 52 °C for 1 h and washed twice for 1 h at 52 °C in hybridisation solution containing $0.5\times\text{SSC}$. The filter was finally rinsed with $2\times\text{SSC}$, dried and exposed to X-ray film for 12 h. The lanes contain: a, pSCP111; b, M146 DNA (SCP1*, SCP2*); c, M130 DNA (SCP1*, SCP2*); d, M110 DNA (SCP1*, SCP2*); e, A332 DNA (chromosomally integrated SCP1, SCP2*); f, SCP2*.

The stability of each of the SCP2* derivatives was determined in *S. coelicolor* (Table 1). The stabilities of SCP2*, pSCP101 and pSCP102 were also examined in *S. lividans* after introduction of the plasmids into this species by either mating (SCP2*) or transformation (pSCP101 and pSCP102). As shown in Table 1, the pSCP111, pSCP101 and pSCP102 derivatives were significantly more unstable than the parental SCP2* plasmid in both *S. coelicolor* and *S. lividans*. However, in *S. coelicolor*, addition of the *Pst*I-B fragment of SCP2* in either orientation to the plasmid derivative totally restored stability to the level shown by SCP2*. These observations are analogous to those made by P. A. Meacock and S.N.C. for *E. coli* plasmids¹⁸; they have isolated a region of pSCP101 that accomplishes the active partitioning of plasmid molecules in dividing cells. We suggest that the *Pst*I-B fragment of the *Streptomyces* plasmid SCP2* may also carry information for partitioning of the plasmid between dividing cells. However, definitive studies of the segregation of plasmids are difficult in a mycelial organism which

may contain several chromosomal genomes per cell and which undergoes a complex process of differentiation and sporulation.

The transfer properties of the plasmid vectors and their abilities to promote chromosomal recombination were also studied. Examination of the fertility properties of each of the SCP2* derivatives (Table 2) indicates that SCP2* increases the level of chromosomal recombination approximately 10^5 -fold over that observed in the absence of any plasmids and that this plasmid is transferred at a frequency of 100% to the recipient culture⁶. Each of the derivatives of this plasmid had fertility and transfer properties similar to those of the parent, indicating that the fertility determinants of SCP2* as well as the transfer functions are located in the region of the plasmid genome covered by the *Pst*I-A and *Bam*HI-A fragments.

In experiments analogous to those described above, isolates were obtained from the *S. lividans* transformation mixture (Fig. 2) that elicited lethal zygosis against *S. lividans* 1326. Plasmid DNA extracted from these clones was analysed by digestion with *Pst*I or *Eco*RI endonucleases and shown to consist of the larger *Pst*I fragment of SLP1.2. This derivative, designated pSLP101, contains unique *Pst*I and *Bam*HI sites located in a non-essential region of the plasmid; one of the sites for both *Hind*III and *Sal*I also occurs in this region. This plasmid is potentially useful for the cloning of DNA fragments produced by any of these four enzymes.

Conclusions

The findings reported here demonstrate the practicality of DNA cloning and heterospecific expression of cloned genes in *Streptomyces*. Because transformation of *Streptomyces* protoplasts is highly efficient, it is possible to clone genes from the chromosome of donor DNA preparations. One of the vectors we have constructed (pSCP111) replicates and expresses resistance to methylenomycin in at least three different *Streptomyces* species, each of which produces at least one antibiotic (refs 11, 19, 20 and M.B., unpublished). Each vector contains an antibiotic resistance determinant that is directly and easily selectable in most *Streptomyces* species and has single cleavage sites in non-essential regions for several different restriction endonucleases, some of which yield DNA termini especially useful for cloning a wide variety of differently generated fragments. For example, DNA fragments generated by *Bgl*II, *Bcl*I, *Sau*3A or *Mbo*II have protruding 5' ends identical to those produced by *Bam*HI and can be cloned at the *Bam*HI site of these vectors. In addition, fragments of chromosomal DNA produced by random shearing can be introduced into the *Pst*I cleavage site by a dG-dC homopolymeric tailing procedure (for example, see ref. 21).

The ability to clone genes in *Streptomyces* should prove valuable in the analysis and, ultimately, the manipulation of antibiotic synthetic pathways of these organisms²². Such manipulation may enable new antibiotics to be produced by the introduction of exogenously derived enzymes that modify pre-existing antibiotics or lead to the synthesis of hybrid antibiotic molecules. In addition, the cloning on multi-copy plasmids, such as pSLP101, of genes involved in rate-limiting biosynthetic steps may prove useful in increasing the yield of antibiotics produced by *Streptomyces* species.

²H NMR study of molecular motion in collagen fibrils

Lynn W. Jelinski, C. E. Sullivan & D. A. Torchia

Laboratory of Biochemistry, National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland 20205

Collagen was labelled through tissue culture with [3,3,3-*d*₃]alanine. ²H NMR spectra were obtained of the labelled collagen as fibrils and in solution using the quadrupolar echo technique for solids. The ²H NMR data were analysed in terms of a model for reorientation in which the molecule is considered to jump between two orientations in a time which is short compared to the residence time in each site, and short compared to $(\Delta\nu_q)^{-1}$. The best fit of the data indicates that the collagen molecule in the fibrils experiences reorientation about its long axis over an angular range of ~30–40°. The *T*₂ for [3,3,3-*d*₃]alanine-labelled collagen fibrils is estimated to be ~110 μs.

CURRENT information about the spatial distribution of amino acids in the collagen molecule has mainly come from X-ray fibre diffraction and model building^{1–4}. These methods, by their nature, lead to a concept of a static collagen molecule in the fibril. We report here ²H NMR results which, in conjunction with previous ¹³C NMR results^{5,6}, require a motionally dynamic model for the collagen molecule in the fibril. We have used solid state ²H NMR of [3,3,3-*d*₃]alanine-labelled collagen to obtain information about molecular motion of the collagen peptide backbone in the fibrils, and to obtain preliminary information on the orientation of the C^α–C^β bond axis of alanine residues in the collagen molecule. In addition, we present equations which allow a simple calculation of the ²H NMR lineshape in the presence of motion. These results provide strong evidence that the peptide backbone in collagen fibrils undergoes rapid ($\tau_c \sim 10^{-7}$ s) motion about the long axis of the molecule and that this motion takes place over an ~30–40° range in azimuthal angle. To our knowledge, this work represents the first application of solid state ²H NMR as a probe for the molecular dynamics of a labelled protein, although this technique has been used very successfully in the membrane field⁷.

Solid state ²H NMR is well suited for the study of molecular motion for several reasons. First, relaxation in ²H NMR is dominated by the quadrupolar interaction, and therefore no questions arise concerning the source of the relaxation mechanism in ²H NMR. Second, the deuterium field gradient tensor for most C–D bonds is generally axially symmetric with the unique principal axis along the C–D bond direction⁸, which makes spectral interpretation straightforward. Third, ²H NMR quadrupolar powder patterns are sensitive to motions which have correlation times $\tau \approx (\Delta\nu_q)^{-1}$, where $\Delta\nu_q$ is the deuterium quadrupole splitting⁷. Fourth, the low natural abundance (0.016%) of deuterium virtually eliminates background signals due to unlabelled material in natural abundance.

Labelling of collagen and measurement of spectra

Lathyrus collagen was labelled with [3,3,3-*d*₃]alanine through chick calvaria culture by previously described methods^{5,6}. Characterisation of the protein by amino acid analysis indicated that it was pure collagen⁹. Optical rotatory dispersion at 313 nm (ref. 10) established that the entire collagen sample was in native form on completion of the ²H NMR experiments. The per cent

incorporation of deuterated alanine in the protein was determined by chemical ionisation gas chromatography–mass spectroscopy of *N*-acetyl methyl ester derivatives^{5,6} of the enzymatically hydrolysed protein. A small amount of proton exchange occurs at alanine during acidic hydrolysis of proteins¹¹. An enzymatic hydrolysis procedure (Pronase and aminopeptidase M) was therefore developed for collagen to avoid artefacts introduced by acid-catalysed exchange on the determination of the per cent incorporation of ²H. Radiotracer analysis (both ³H and ¹⁴C) indicated that no amino acids other than alanine were labelled during biosynthesis. The labelled collagen was studied by ²H NMR both in solution (~10 mg ml⁻¹ in 0.1 M acetic acid) and as fibrils (in equilibrium with 0.02 M Na₂HPO₄). ²H NMR spectra were obtained using a 'home-built' spectrometer operating at 5.2 T (33.78 MHz for ²H). The $\pi/2$ pulse was 5 μs. A solid echo pulse sequence ($90^\circ_{\pm x} - t_1 - 90^\circ_y - t_2 - T$) (refs 12–14) was used for all experiments to preserve the inhomogeneously broadened portion of the NMR signal, which is normally lost through spectrometer dead time. The phase of the first 90° pulse was shifted by 180° on alternate scans to reduce artefacts due to coil ringing and imperfect 90° pulses. All data were acquired in quadrature (2,000 points per channel) with a sampling rate of 5 μs per point. Signal distortion due to pulse power fall-off was less than 10% over the range ±40 kHz, and the lineshapes presented here were not corrected. A control ²H NMR spectrum of unlabelled collagen was run for every ²H NMR spectrum of labelled collagen discussed here. This ensured that the portion of the signal arising from [3,3,3-*d*₃]alanine-labelled collagen and the portion arising from deuterated water in natural abundance could be assigned with confidence.

Analysis of the spectra

The ²H NMR spectra for L-[3,3,3-*d*₃]alanine and for various alanine-labelled collagen samples are presented in Fig. 1. As a powdered amino acid, L-[3,3,3-*d*₃]alanine exhibits the classical ²H NMR powder pattern (Fig. 1*a*). The observed quadrupolar splitting ($\Delta\nu_q = (3e^2qQ/4h)(3\cos^2\theta' - 1)/2$) of 38.8 kHz (Table 1) shows that the static quadrupolar coupling constant ($e^2qQ/h \approx 165$ kHz) has been averaged to approximately one-third of its value by rapid rotation of the methyl group¹⁵. Frozen [3,3,3-*d*₃]alanine-labelled collagen fibrils (Fig. 1*b*) exhibit a ²H NMR lineshape similar to that of the powdered amino acid. The

Fig. 1 Experimental ^2H NMR spectra for $[3,3,3\text{-d}_3]$ alanine and $[3,3,3\text{-d}_3]$ alanine-labelled collagen. These spectra were obtained in quadrature using the solid echo pulse sequence ($90^\circ_{\text{xx}} - t_1 - 90^\circ_{\text{yy}} - t_2 - T$) with t_1 and t_2 set at 50 and 59 μs , respectively. *a*, $[3,3,3\text{-d}_3]$ Alanine as a polycrystalline amino acid; 256 accumulations, 0.25 s repetition rate, 18 $^\circ\text{C}$; *b*, $[3,3,3\text{-d}_3]$ alanine-labelled collagen fibrils, 20 mg in equilibrium with excess Na_2HPO_4 ; 2×10^5 accumulations, 0.25 s repetition rate, -18 $^\circ\text{C}$; *c*, the same as in *b*, except at 18 $^\circ\text{C}$; *d*, $[3,3,3\text{-d}_3]$ alanine-labelled collagen in solution, ~ 10 mg/ml in about 0.4 ml 0.1 M acetic acid in deuterium-depleted water; 2.5×10^5 accumulations, 0.1 s repetition rate, 18 $^\circ\text{C}$; *e-h*: calculated spectra for $[3,3,3\text{-d}_3]$ alanine and for $[3,3,3\text{-d}_3]$ alanine-labelled collagen. Lorentzian line-broadening was used in all cases; *e*, calculated spectrum of polycrystalline $[3,3,3\text{-d}_3]$ alanine; $\Delta\nu_q = 38.8$ kHz, line-broadening = 1.3 kHz; *f*, Calculated spectrum of frozen $[3,3,3\text{-d}_3]$ alanine-labelled collagen fibrils; $\Delta\nu_q = 37.3$ kHz, line-broadening = 1.5 kHz; *g*, Calculated spectrum of $[3,3,3\text{-d}_3]$ alanine-labelled collagen fibrils at 18 $^\circ\text{C}$. The alanine $\text{C}^\alpha\text{-C}^\beta$ bond axes are assumed to undergo jump diffusion between two equally populated sites. The angles θ between the $\text{C}^\alpha\text{-C}^\beta$ bond axes and the helix axis are 69° and 85° (Fig. 2*a, b*). The angle 2δ through which the projected alanyl $\text{C}^\alpha\text{-C}^\beta$ bond axis is carried by reorientation of the peptide backbone is 40° (Fig. 2*b, c*). The spectra calculated for $\theta = 69^\circ$ and $\theta = 85^\circ$ were summed with equal weight; $\Delta\nu_q = 37.3$ kHz, line-broadening = 4.1 kHz. A Lorentzian signal with 600 Hz linewidth was included in the centre of the spectrum to simulate the natural abundance signal from water. *h*, Calculated spectrum of $[3,3,3\text{-d}_3]$ alanine-labelled collagen in solution. Reorientation of the alanyl $\text{C}^\alpha\text{-C}^\beta$ bond axis about the long axis of the helix has averaged the crystalline 37.3 kHz quadrupolar splitting to ~ 10 kHz. Line-broadening = 4.1 kHz.

quadrupolar splitting for the frozen fibrils is about 3% smaller than for the labelled amino acid (Table 1). This result may arise from a small amount of molecular motion (in addition to methyl rotation) which occurs in the fibrils at -18 $^\circ\text{C}$, or may reflect a slightly smaller quadrupolar coupling constant for alanine in a polypeptide.

At +18 $^\circ\text{C}$, $[3,3,3\text{-d}_3]$ alanine-labelled collagen fibrils exhibit a ^2H NMR spectrum in which about 60% of the signal intensity is lost and in which the singularities are no longer well defined (Fig. 1*c*; Table 1). To establish that the observed lineshape (Fig. 1*c*) was representative of the entire sample, a spectrum was obtained at the shortest values of t_1 and t_2 which were consistent with recovery of the spectrometer (30 and 39 μs , respectively). This spectrum contained more intensity, but was identical in shape (within uncertainty due to baseline distortion) to the spectra obtained at longer t_1 and t_2 values. The apparent reduction of the quadrupolar splitting and the loss of signal intensity

through homogeneous T_2 processes¹⁶ observed in Fig. 1*c* imply reorientation of the alanine methyl in collagen fibrils in addition to 3-fold rotation. Motion of the alanine methyl group (the $\text{C}^\alpha\text{-C}^\beta$ bond axis) requires reorientation of the peptide backbone in collagen because alanine contains no additional bonds about which reorientation can take place.

The ^2H NMR spectrum of $[3,3,3\text{-d}_3]$ alanine-labelled collagen in solution shows a further reduction of the spectral width (Fig. 1*d*; Table 1). In solution, collagen behaves as a rod-like monomer of molecular weight 285,000 and dimensions of $\sim 1.5 \times 300$ nm¹⁷. The molecule in solution can undergo free rotation about its long axis, ($R_1 \sim 10^7$ s⁻¹), whereas end-over-end rotation is slow ($R_2 \sim 10^2$ s⁻¹) and is restricted at these concentrations due to occupied volume considerations^{5,6}. Accordingly, the ~ 37 -kHz quadrupolar splitting observed for the frozen labelled fibrils would be expected to collapse by a factor of $(1-3\cos^2\theta)/2$ in the presence of free rotation about the long axis of the collagen molecule. Here, θ is the angle formed between the $\text{C}^\alpha\text{-C}^\beta$ bond axis and the long axis of the molecule (Fig. 2*a*). The observed quadrupolar splitting for labelled collagen in solution is ~ 10 kHz, which requires that θ be $\sim 70^\circ$. An angle of $\sim 70^\circ$ for θ is in good agreement with the $\text{C}^\alpha\text{-C}^\beta$ bond angles predicted by various models for the collagen helix^{1,3,18} which place θ between 60° and 90° . Comparison of the ^2H NMR intensity from the labelled sample with the intensity from the same amount of unlabelled collagen (deuterium-depleted water used in both cases) indicates that about half the intensity of the sharp peak in Fig. 1*d* arises from the alanine-labelled protein in solution and that the rest is due to deuterated water in natural abundance. Previous ^{13}C NMR experiments^{5,6},

Fig. 2 Schematic representation of the alanine methyl group attached to the collagen helix. *a*, The collagen helix considered as an ellipsoid. The $\text{C}^\alpha\text{-C}^\beta$ bond of alanine makes the angle θ with the long axis of the helix; *b*, the methyl group of alanine, which makes an angle θ with respect to the helix axis (the z axis), undergoes reorientation between two sites separated by an angle 2δ ; *c*, Cross-section of collagen molecules assembled into fibrils. The molecules undergo reorientation about the long axis of the helix over an azimuthal angle of 2δ .

Table 1 Quadrupolar splitting ($\Delta\nu_q$) for [3,3,3- d_3]alanine and [3,3,3- d_3]alanine-labelled collagen fibrils

Sample	$\Delta\nu_q^*$ (kHz)
[3,3,3- d_3]Alanine	38.8
[3,3,3- d_3]Alanine-labelled collagen fibrils in 0.02 M Na_2HPO_4	
-18°C	37.3
+18°C	~30†
lyophilised	38
[3,3,3- d_3]Alanine-labelled collagen in solution	~10†

* $\Delta\nu_q = \frac{3e^2qQ}{4h} (3 \cos^2 \theta' - 1)/2$; θ' is the angle made by the $\text{C}^\alpha\text{-C}^\beta$ -D and $\text{C}^\alpha\text{-C}^\beta$ bond axes.

†Axially asymmetric pattern; value reported is the frequency difference between maxima in the calculated spectrum and corresponds to the apparent splitting.

in conjunction with the present sample characterisation, indicate that it is unlikely that this peak is due to a small amount of denatured protein. However, the sharp component may be due to some alanine $\text{C}^\alpha\text{-C}^\beta$ bond axes which make the 'magic angle' (54.7°) with respect to the helix axis, or to the 3% of the alanine residues which reside in the non-helical termini of the molecule².

The ^2H NMR spectra of labelled collagen fibrils were analysed by matching the experimental lineshapes with lineshapes calculated in the presence of molecular reorientation. In the motional model utilised for these calculations, the molecule is considered to jump between two orientations in a time which is much less than the residence time in each of the two sites¹⁹ and much less than $(\Delta\nu_q)^{-1}$.

The assumed motion of the collagen backbone makes the alanine $\text{C}^\alpha\text{-C}^\beta$ bond axis jump between two orientations, labelled 1 and 2 in Fig. 3a. As a consequence of the motion, the observed powder pattern will not generally be axially symmetric. Using Fig. 3a, one can determine the principal axis system (x, y, z) and the frequencies ($\omega_x, \omega_y, \omega_z$) corresponding to the principal values of the motionally averaged field gradient tensor as follows. For clarity we consider the powder pattern corresponding to the transition for which $\omega_\perp \leq \omega \leq \omega_\parallel$ (see Fig. 3b). When H_0 (the applied field) is normal to the 1, 2 plane, $\omega = \omega_\perp$ in both the 1 and 2 orientations. Since this is the minimum value possible for ω , x must be normal to the 1, 2 plane (we use the convention $\omega_x \leq \omega_y \leq \omega_z$) and $\omega_x = \omega_\perp$. The remaining principal axes, y and z , are perpendicular to x and are thus in the 1, 2 plane. When H_0 is in this plane:

$$\begin{aligned}\omega &= 0.5[\omega_\parallel(\cos^2 \theta_{1H} + \cos^2 \theta_{2H}) \\ &\quad + \omega_\perp(\sin^2 \theta_{1H} + \sin^2 \theta_{2H})] \\ \omega &= -0.5\omega_\perp[3 \cos^2 \theta_{1H} + 3 \cos^2(\gamma_{12} - \theta_{1H}) - 2]\end{aligned}$$

where θ_{1H} and θ_{2H} are the respective angles made by H_0 with 1 and 2. When H_0 lies along z , ω is maximal, and solving the equation $d\omega/d\theta_{1H} = 0$ shows that z bisects γ_{12} when γ_{12} is in the first or fourth quadrants, and that z is perpendicular to the bisector of γ_{12} when $90^\circ \leq \gamma_{12} \leq 270^\circ$. The y axis is normal to the xz plane. The frequencies corresponding to the field along the principal axes are

$$\begin{aligned}\omega_x &= \omega_\perp \\ \omega_y &= -\omega_\perp[3 \sin^2(\gamma_{12}/2) - 1] \\ \omega_z &= -\omega_\perp[3 \cos^2(\gamma_{12}/2) - 1]\end{aligned}$$

These results apply for γ_{12} in the first or fourth quadrant. When $90^\circ \leq \gamma_{12} \leq 270^\circ$, the expressions for ω_y and ω_z are interchanged. Note that an axially symmetric pattern occurs only when $\gamma_{12} = 0, 90$ or 270° (Fig. 3b), and a pattern having $\eta = 1$ occurs whenever ω_y equals zero (Fig. 3c). The correspondence

between γ_{12} and the angles (θ, δ) which describe the reorientation of the molecule is: $\cos \gamma_{12} = \cos^2 \theta + \sin^2 \theta \cos^2 2\delta$.

The relevant angles which describe the orientation of the alanine methyl group in the collagen molecule are shown in Fig. 2. The angle formed by the alanine $\text{C}^\alpha\text{-C}^\beta$ bond axis and the long axis of the collagen helix is designated as θ (Fig. 2a,b). The angle δ is half of the angle through which the alanine $\text{C}^\alpha\text{-C}^\beta$ bond is carried by reorientation of the peptide backbone (Fig. 2b,c).

The various collagen models predict that the angle which the $\text{C}^\alpha\text{-C}^\beta$ bond makes with the helix axis depends on whether the considered amino acid occurs in the X or Y position of the Gly-X-Y triplet sequence^{1,3,18}. Accordingly, the lineshapes from two representative values of θ (85° and 69°) were summed with equal weight (alanine is distributed equally in the X and Y positions in collagen) for each calculated spectrum. The angle δ and the line broadening were varied until the best match of the lineshape was obtained.

Fig. 3 a, The geometrical construction used to deduce ω_x, ω_y and ω_z in the presence of two-site jump reorientation. 1 and 2 refer to the two orientations between which the alanine $\text{C}^\alpha\text{-C}^\beta$ bond axis is considered to jump. The angles θ, δ , and γ_{12} are described in the text; b, a theoretical axially symmetric powder pattern (one transition for the case when $\eta = 0$); c, the theoretical pattern expected when $\eta = 1$ (when $\omega_y = 0$). In the presence of line-broadening, this pattern would lose definition in the edges and have an overall tent-like appearance.

Implications for models of collagen

The best fit of the data (Fig. 1c,g) indicates that the collagen molecule in the fibril undergoes reorientation over a $\sim 30\text{--}40^\circ$ range in azimuthal angle (that is, $2\delta \approx 30\text{--}40^\circ$; Fig. 2c). This angle is in good agreement with an estimate obtained from previous ^{13}C NMR studies^{5,20} in which the minimum angle, 2δ , consistent with the ^{13}C T_1 data, was $\sim 30^\circ$. The assumption used in the calculations of the ^2H NMR lineshapes (that the jump rate is much larger than $\Delta\nu_Q$) is consistent with the reorientation rate of about 10^7 s^{-1} , derived from the ^{13}C studies^{5,6,20}. A line-broadening of $\sim 4\text{ kHz}$ is required to fit these ^2H NMR data. A portion of this line-broadening ($\sim 3\text{ kHz}$) can be explained by the T_2 , which we estimate to be $\sim 110\text{ }\mu\text{s}$. The rest of the line-broadening is attributed to D-H dipolar interactions. Mass spectroscopic analysis showed that of the alanine residues which were labelled, about half contained three deuterons, one quarter

contained two deuterons, and one quarter contained one deuteron. Note that the partial loss of deuterons from alanine must occur during biosynthesis as mass spectroscopy indicates that $\sim 95\%$ of the starting $[3,3,3\text{-d}_3]\text{alanine}$ and $\sim 95\%$ of the control labelled alanine for the enzymatic hydrolysis contained three deuterons. A second moment calculation⁸ indicates that the static D-H interaction between a deuteron and a single proton on the same alanine methyl carbon²¹ causes an average line-broadening of $\sim 3.5\text{ kHz}$. Three-fold rotation of the methyl group would average this to $\sim 1.7\text{ kHz}$.

The ^2H NMR results presented here, in conjunction with earlier ^{13}C NMR results^{5,6,20}, provide strong evidence that the peptide backbone in collagen fibrils undergoes rapid ($\tau_c \leq 10^{-7}\text{ s}$) anisotropic motion about the long axis of the molecule. The range in azimuthal angle over which this motion takes place is estimated to be $30\text{--}40^\circ$.

The γ -ray background and the age of protogalaxy formation

G. Cavallo

Laboratorio TESRE/CNR, Via De' Castagnoli 1, 40126 Bologna, Italy

A. Di Fazio

Laboratorio di Astrofisica Spaziale, C. P. 67, 00044 Frascati, Italy

The diffuse γ -ray background which is implied by the current models of protogalaxy formation is considered here in an attempt to set limits to the redshift z_i of that event. This is obtained by observing that cosmic rays from supernovae exploding in protogalaxies produce an isotropic γ -background in excess of the observed values if protogalaxies form too early. Without any special assumptions, the constraints on z_i turn out to be more significant than any other limit previously reported. In fact, for z_i to be >100 , one must postulate either a very low cosmic ray production in supernovae, or a very low density of intergalactic gas, that is, $<10^{-10}\text{ cm}^{-3}$, or both.

We consider only specific cases which set the age of galaxy formation at a redshift $z_i \leq 100$. In this case, even for a 'dense interstellar gas universe' ($n_0 \approx 10^{-5}\text{ particles cm}^{-3}$), all proton and photon absorption and degradation effects become minimal, and we can consider the simplified model of γ -ray propagation in a vacuum by thin target scattering.

In contrast, if $z_i \geq 100$, a different model, which can be simplified according to Cavallo and Rees¹, and Cavallo and Pacini² should be used. However, the predictions of this second approach depend critically on the precise shape of the 'fireball' photon spectrum in the neighbourhood of 0.5 MeV, a shape that has not yet been reported. Therefore, we shall only consider the simpler case $z_i \leq 100$, which already gives some interesting results.

The circumstances of protogalaxy formation are well known: at a given z_i , appropriate light element gas clouds collapse and

fragment, producing first generation stars. These stars will evolve according to canonical models, and will manufacture the heavier elements which will then be found in the second generation stars. Supernova explosions will expel and mix these heavier elements in the interstellar gas, and their abundances can presently be observed.

Note that supernovae are also thought to be the source of cosmic ray energy. Cosmic rays in their turn will produce γ -rays through the decay of neutral mesons produced in collisions with the interstellar gas. Current views, therefore, suggest that when protogalaxies formed light gas was converted into heavier elements and cosmic rays. Such a conversion into high energy particles might be approximated by a burst of cosmic rays taking place at a certain time z_b , in general quite close to z_i . In turn, such a burst might be incompatible with the presently observed γ -ray flux. To calculate a minimum value for the γ -ray background, we assume that cosmic rays directly or indirectly receiving their energy from supernova explosions interact mainly with the intergalactic gas. If the galaxies or, worse, the remnants, were opaque to cosmic rays, the energy conversion into γ -rays would be much more efficient, and our limits on z_i would thus be significantly lowered. Similarly, our results would be strengthened if the origin of the γ -background were not due to the mechanisms considered here.

The relevant computations go back to Stecker³ and Cavallo⁴, who obtained substantially similar results. The differential flux observed at $z = 0$ is given by

$$I_\gamma(E_\gamma) = cn_0 H_0^{-1} \int_0^{z_b} G_\gamma(E_\gamma; 1+z) \times (I(z)/I_0)(1+z)^{-5/2} dz \quad \text{photons cm}^{-2} \Delta E^{-1} \quad (1)$$

Here we have assumed that the cosmic ray flux $I(z)$ has the same energy dependence as I_0 , the presently observed galactic cosmic ray flux; moreover, an Einstein-de Sitter model has been adopted. The function $G_\gamma(E)$ is the differential specific emissivity produced by collisions of the galactic cosmic ray flux with the

interstellar gas in a 1-cm pathlength. One can show that, for $E_{\gamma e} = E_{\gamma o}(1+z)$ (subscripts e and o refer to emitted and observed respectively) the differential emissivity becomes: $G_k(E; 1+z) = (1+z)G_k[(1+z)E_{\gamma}]$. For a burst model, one has³:

$$I(z)/I_g = A(1+z)^3(1+z)^{3/2}(1+z_b)^{-3/2} \quad (2)$$

where one should observe the normalisation $I_o/I_g = A(1+z_b)^{-3/2}$. Thus the integral becomes:

$$I_{\gamma}(E_{\gamma}) = cn_0 H_0^{-1} A(1+z_b)^{-3/2} \int_0^{z_b} G_k[E_{\gamma}(1+z)](1+z)^3 dz \quad (3)$$

An easy comparison with experiment can be made by integrating the flux for $E_{\gamma} \geq 100$ MeV. If $y = E_{\gamma}(1+z)$, we obtain:

$$I_{\gamma}(E_{\gamma} > 100 \text{ MeV}) = cn_0 H_0^{-1} A(1+z_b)^{-3/2} \int_0^{z_b} (1+z)^2 dz \times \int_{100 \text{ MeV}/(1+z)}^{\infty} G_k(y) dy \quad (4)$$

Above 100 MeV and for $z \geq 3$ (a value comparable with the maximum z observed in QSOs) a good approximation is the relationship

$$\int_{(1+z)100 \text{ MeV}}^{\infty} G_k(y) dy = 2 \times 10^{-25} (1+z)^{-3/2} \quad (5)$$

Therefore:

$$I_{\gamma}(E_{\gamma} > 100 \text{ MeV}) = 2 \times 10^{-25} cn_0 H_0^{-1} (I_o/I_g)(2/3)[(1+z_b)^{3/2} - 1] \quad (6a)$$

$$\approx 1.3 \times 10^{-25} cn_0 H_0^{-1} (I_o/I_g)(1+z_b)^{3/2} \quad \text{for } z_b \gg 1 \quad (6b)$$

Equation (6b), divided by 4π , may be compared with the flux 1×10^{-5} photons $(\text{cm}^2 \text{s sr})^{-1}$, given in ref. 5, smaller by a factor of 10 than the flux adopted by Stecker³. The desired result is, therefore,

$$I_o/I_g \leq [1 \times 10^{-2}](1+z_b)^{-3/2} h_{100} n_5^{-1} \quad (7)$$

where $h_{100} = H_0/(100 \text{ km s}^{-1} \text{ Mpc}^{-1})$ and $n_5 = n_0/(10^{-5})$. Equation (7) gives a good approximation to the values given in ref. 3, apart from the factor of 10 mentioned above. The theory of star formation gives some indication of the value of I_o/I_g . Our model assumes that a fraction of $\sim 2.8 \times 10^{-6} E_{50}$ protons per supernova of at least $6 M_{\odot}$ goes into cosmic rays. Here, E_{50} is the total energy emitted in cosmic rays of average energy 3 GeV, measured in units of 10^{50} erg. If all matter had gone through the supernova stage, the ratio I_o/I_g would be $\sim E_{50}/4$ at present. In fact, only an appropriate fraction $f(z_b)$ of all matter went into supernovae, specifically, only those stars whose mass exceeds $\sim 6 M_{\odot}$. The general result is therefore:

$$f(z_b)(1+z_b)^{3/2} \leq [1 \times 10^{-2}](E_{50}/4)^{-1} h_{100} n_5^{-1} \quad (8)$$

Here a method of computing $f(z_b)$ is used based on current fragmentation models, which predict a specific minimum mass M_{ff} for the ultimate fragments. M_{ff} depends on the background temperature according to the law⁶:

$$M_{\text{ff}} = 1.54 \times 10^{-3} (m_{\text{H}}/m)^2 T_b^2 (k_{\text{pt}}/k_0) M_{\odot} \quad (9)$$

with $T_b = 2.7(1+z)\text{K}$; m_{H} and m are the mass of the hydrogen atom and of the typical atom of the fragmenting gas cloud, k_{pt} is the final Planck mean opacity per unit mass, and k_0 is the opacity due to free electron scattering in ionised hydrogen. The existence of such a temperature dependent minimum mass ensures us that the earlier the protogalaxies formed, the more complete was the conversion of light gas into heavier elements and cosmic rays.

Assuming a Salpeter⁷ initial mass function $\psi(m) = K m^{-2.3}$, we can write:

$$f(z_b) = \int_{6M_{\odot}}^{\infty} m\psi(m) dm / \left(\int_{M_{\text{ff}}}^{\infty} m\psi(m) dm \right) \quad (10)$$

which becomes:

$$f(z_b) = \begin{cases} 0.15(1+z_b)^{0.6} & \text{for } z_b \leq 22.12 \\ 1 & \text{for } z_b \geq 22.12 \end{cases} \quad (11a)$$

$$(11b)$$

Consequently one should satisfy the relationship:

$$0.27 \geq (1+z_b)^{21/10} E_{50} n_5 h_{100}^{-1} \quad \text{for } z_b \leq 22 \quad (12a)$$

$$4 \times 10^{-2} \geq (1+z_b)^{3/2} E_{50} n_5 h_{100}^{-1} \quad \text{for } z_b \geq 22 \quad (12b)$$

Thus, in general to have $z_b \geq 3$, one needs $\epsilon E_{50} n_5 h_{100}^{-1} \leq 1.5 \times 10^{-2}$ where ϵ is the efficiency of protogalaxy formation. The current value $\epsilon = 1$, and we conclude that in this framework ($n = 10^{-5} \text{ cm}^{-3}$) there is no chance of finding an appropriate z_b . The only effective possibility is that of lowering n_0 to, say, 10^{-7} cm^{-3} . In this case we would obtain:

$$1+z_b \approx 4.8 (E_{50} n_7 h_{100}^{-1})^{-10/21} \quad (13)$$

and we suggest this value of $z_b \approx 4$ as a possible burst age. An intergalactic gas density of $< 10^{-10}$ is needed to achieve $z_b \geq 100$. Of course, this does not mean that we favour an open universe: we can only say that the intergalactic gas is likely to give an irrelevant contribution to the average matter density of the universe.

The foregoing results depend on some common assumptions which we now examine.

(1) The validity of equations (9) and (10): In fact, the $(1+z)$ dependence in equation (9) is weakened in equation (10), and would be practically ineffective for a $\psi(m) = K m^{-2}$ power law. Thus, equation (9) does not strongly affect our results. The possibility that the initial mass distribution is appreciably different from the Salpeter function is more important. One must, however, observe that supernovae are needed for manufacturing heavy elements, without producing too many of them. There are two alternatives: (i) the initial distribution of stars, although non-Salpeter-like, mostly consists of massive stars; (ii) the initial distribution mostly consists of low mass stars. The first alternative, which supports our conclusions, has the risk of producing too many heavy elements, but in the second alternative the minimum mass should be such that supernovae can produce a sufficient amount of heavy elements, without leaving behind too many first generation stars. Therefore, the assumption implicit in equation (10) is not really critical.

(2) The validity of the assumption that each supernova produces 10^{50} erg in cosmic rays. At first, this might seem to be a very uncertain figure, as it depends on two poorly known parameters—the explosion rate and the cosmic ray diffusion coefficient. However, estimates of the total particle content for many remnants⁸, and considerations of the kinetic energy input in remnants, using some equipartition assumptions⁹, all indicate a rather restricted range of values around and perhaps greater than $E_{50} = 1$. A finer point is to consider the fate of the protons thus produced. It is commonly assumed that the energy requirements for cosmic rays are met by supernovae: the cosmic rays might directly come from the first stages of the explosion (as in the Colgate¹⁰ model) or the energy of supernovae might be used to accelerate cosmic rays by interstellar shocks. In both cases our results will stand.

(3) Finally, protogalaxy formation might have a small efficiency. Hogan and Layzer¹⁰ made similar assumptions to explain the microwave and X-ray background, but they had to resort to a high yield of relativistic electrons per supernova ($3-7 \times 10^{48}$ erg). The above criticisms also apply to their model, but our results on z_b turn out to be more restrictive, while giving information about the intergalactic gas density which the previous authors could not consider. Our stricter limits, apart from minor technical details, such as the assumption of an Einstein-de

Sitter universe with a slightly higher conversion of particles into relativistic cosmic rays, result from the following: (1) the multiplicity of meson production is >1 and increases with energy; (2) there are about 100 times more protons than electrons in cosmic rays; (3) most important of all, the energy content of the diffuse X-ray background exceeds by about two orders of magnitude the energy content in the isotropic γ -ray background.

Therefore we believe that γ -ray astronomy is still one of the most useful sources of information on the early universe.

We thank the Institute of Astronomy in Cambridge for hospitality, and Prof. M. J. Rees for his criticisms. G. C. acknowledges exchange programme sponsored by the Royal Society and the Accademia Nazionale dei Lincei.

Inhibition of diffusion by the reflection effect in binary Hg–Mn stars

B. N. G. Guthrie & W. M. Napier

Royal Observatory, Blackford Hill, Edinburgh EH9 3HJ, UK

The Hg–Mn stars constitute a sub-group of the peculiar A stars which have abundance anomalies in their atmospheres. Their distinctive properties are excesses of P, Mn, Ga, Y and Hg¹, slow rotation², a high frequency of double-lined spectroscopic binaries^{3,4}, and a lack of detectable magnetic fields⁵. It is widely believed that the abundance anomalies are at least partly due to the separation of elements by diffusion under the influence of gravitation and radiation pressure^{6,7}. For the diffusion mechanism to operate the atmosphere has to be extremely quiescent with circulation velocities $\leq 10^{-3} \text{ m s}^{-1}$. We point out here that in a spectroscopic binary system with similar components surface streaming velocities greatly in excess of this value are expected due to the mutual irradiation of the components.

The mutual irradiation creates temperature gradients over the respective surfaces of the binary components; hydrostatic equilibrium cannot be maintained and streaming away from the substellar points must occur. The mean effective temperature, T , over each illuminated hemisphere is given by

$$T^4 \sim T_0^4(1+f)$$

T_0 being the effective temperature of the averted hemispheres and f being the fraction of radiation from one star intercepted by the other. For a mean component separation a and a component radius R ,

$$f \sim 1/4(R/a)^2$$

The horizontal temperature gradient produces a horizontal pressure difference ΔP which drives a streaming motion with characteristic velocity v . Thus for a characteristic photospheric density ρ

$$\Delta P \sim \frac{1}{2}\rho v^2$$

which with the gas equation, and in the absence of a significant magnetic field and radiation losses, yields

$$v \sim 0.18 (\Delta T)^{1/2} \text{ km s}^{-1}$$

where

$$\Delta T = T - T_0 \sim T_0 f/4$$

(compare with ref. 8 where a coefficient 0.36 was derived by approximate application of the equation of motion).

The periods of known Hg–Mn spectroscopic binaries range from 3 to 560 days; 13 of the 22 known binaries have periods of less than 10 days, and eight of these are double-lined with mass ratios near unity^{3,4}. For a typical Hg–Mn binary with a period of 6 days and components of masses $\sim 6M_\odot$, $a \sim 2 \times 10^{10} \text{ m}$. With $R \sim 2.7 \times 10^9 \text{ m}$, $f = 4.6 \times 10^{-3}$. Taking $T_0 \sim 14,000 \text{ K}$, one finds $\Delta T \sim 16 \text{ K}$ and $v \sim 700 \text{ m s}^{-1}$. Radiative losses are likely to reduce v by a factor of $\sim 10^2$ (ref. 9). Thus the characteristic streaming velocity will be $\sim 7 \text{ m s}^{-1}$. This velocity is four orders of magnitude greater than those envisaged on the diffusion mechanism. The Reynolds number is $\geq 10^7$ and the streaming is turbulent. Then the ratio of mixing to diffusive time scales is simply the ratio of the respective velocities, and so the photospheric layers will mix on a time scale $\leq 10^{-4}$ of the segregation time for diffusion in a quiescent atmosphere.

The question arises whether a magnetic field might constrain the motion. Equating magnetic and kinetic energies,

$$H^2/8\pi \sim \frac{1}{2}\rho v^2$$

where H is the magnetic field strength. Hence if $\rho \sim 10^{-9} \text{ g cm}^{-3}$, $H \sim 0.08 \text{ G}$. The threshold of detection of the line-of-sight component of H is $\sim 200 \text{ G}$, and so a magnetic field might possibly constrain the stream motion. It is not clear whether turbulent motions will occur in an atmosphere dominated by a magnetic field. However, even if laminar flow and diffusion occur over restricted regions of the stellar surface, vertical mixing must still take place at the boundaries of these regions.

Synchronous rotation has been assumed in the foregoing discussion. In this case the streaming pattern would be stable, but mixing at the boundary between the illuminated and averted hemispheres might prevent the formation of a spectrum variable. However, measurements of projected rotational velocities⁴ show that Hg–Mn stars in short-period binaries often have rotational periods longer than the orbital periods. With non-synchronous rotation the illumination will affect the various parts of the stellar surface in turn. The flow pattern is quickly established, and so streaming motion will be periodically induced over the entire stellar surface.

The streaming will decrease very rapidly with the optical depth τ , and diffusion at sub-photospheric layers, say $\tau \geq 5$, is not precluded by the reflection effect. However, models accounting for the overabundances and isotopic anomalies of Hg in terms of diffusive segregation at high levels¹⁰ seem to be excluded; almost all Mn stars have large overabundances of Hg (refs 11, 12).

The abundance anomalies of Hg–Mn stars do not seem to be correlated with their measured rotational velocities¹³. Such a correlation might have been expected if all the anomalies were due to diffusion limited only by meridional circulation.

The only current alternatives to diffusion are accretion models involving supernova ejecta¹⁴ or planetary bodies¹⁵ and so on. Simple accretion may produce overabundances but not deficiencies. However, we have not excluded sub-photospheric diffusion, and this may account for some of the observed deficiencies. Thus the explanation of Hg–Mn star anomalies may lie in a combination of accretion and sub-photospheric diffusion mechanisms.

We thank Dr D. T. Wickramasinghe for helpful comments.

Santa Catharina meteorite and phase composition of irradiated Fe–Ni Invar alloys

J. Danon, R. B. Scorzelli & I. Souza-Azevedo

Centro Brasileiro de Pesquisas Fisicas, Av. Wenceslau Bras 71,
Rio de Janeiro, Brasil

J. Laugier & A. Chamberod

Centre d'Etudes Nucléaires de Grenoble, 85X-18041,
Grenoble Cedex, France

The iron meteorite Santa Catharina is an ataxite that contains 35% Ni. Laboratory made Fe–Ni alloys of this composition are called Invar alloys, due to their low thermal expansivity near room temperature. The heterogeneous phase composition of the meteorite, which is apparent from a metallographic examination, has been confirmed by thermomagnetic measurements¹ and by more recent Mössbauer spectra and microprobe analysis². The nature and origin of the alloy phases in Santa Catharina have been the subject of recent investigations^{3,4} and we report here Mössbauer spectra and X-ray diffraction measurements which show that the phase composition of the meteorite is similar to that obtained by electron irradiation of Fe–Ni Invar alloys⁵.

The extensive phase segregation and radiation-induced ordering which occurs in electron irradiated Invar alloys have been observed by small angle neutron scattering⁶ and by Mössbauer spectroscopy⁵. This is illustrated in Fig. 1a, b. One of the phases is paramagnetic and causes the central peak of the spectrum (Fig. 1b), and the other phase is ferromagnetic and causes the magnetic hyperfine splitting of the Mössbauer spectrum. Computer fitting shows that the latter spectrum consists of two six-line spectra which have asymmetric shapes caused by the presence of an electric field gradient which superimposes a quadrupole splitting on the magnetic hyperfine pattern. Both spectra are due to the ordered Fe–Ni phase with the L10 superstructure^{7,8}. One of the two overlapping spectra has an hyperfine magnetic field $H_i = 288$ kG and a quadrupole splitting $\Delta E_Q = +0.23$ mm s⁻¹. This spectrum is caused by large crystallites of the ordered phase having their magnetic axes parallel to the axes of the electric field gradient⁹. Small crystallites may have their magnetic axes perpendicular to the axes of the electric field gradient and thus produce different Mössbauer parameters ($H_i = 310$ kG, $\Delta E_Q = -0.12$ mm s⁻¹).

Figure 1c shows the spectrum obtained with a thin section of the Santa Catharina meteorite showing a well-resolved asymmetric Mössbauer spectrum with a magnetic hyperfine field $H_i = 288$ kG, and quadrupole splitting $\Delta E_Q = +0.20$ mm s⁻¹ and a central peak corresponding to a paramagnetic phase. The Mössbauer parameters corresponding to the magnetic phase shows that this phase in the meteorite is composed only of large crystallites of the ordered alloy with the L10 superstructure, and all their magnetic axes are parallel to the electric field gradient axes.

We have also measured the Mössbauer spectra of the irradiated alloy and of the meteorite in other conditions, such as at low temperatures (4.2 K), with powder absorbers, under the influence of an applied magnetic field up to 50 kG; no obvious differences were observed between the samples.

In Fig. 2, the X-ray diffraction pattern obtained with the unirradiated alloy (35% Ni) is compared with the irradiated alloy and the meteorite sample. Superstructure L10 lines are detected in the irradiated alloy and in the meteorite but with much higher intensity. This corresponds to what was observed in the Mössbauer spectra, that is, that the degree of ordering is much larger in the meteorite compared with that obtained by irradiation of the alloy.

In Fig. 3, the thermal variation of the X-ray lattice parameters of the unirradiated alloy is compared with the irradiated alloy and the meteorite sample.

Fig. 1 Mössbauer absorption spectra recorded at room temperature with a ⁵⁷Co source in Rh of: a, Fe–Ni Invar alloy (35% Ni) before irradiation; b, after irradiation at 80 °C with 4×10^{19} 3-MeV electrons; c polished thin section of the Santa Catharina meteorite.

A large decrease of the lattice parameter, from 3.593 Å (Fig. 3a) to 3.582 Å (Fig. 3b) is observed on irradiating the Invar alloy. The two phases which are formed by irradiation have the same value for the lattice parameter. The Invar properties of the alloy are shown to disappear on irradiation by the linear variation of the lattice parameter with temperatures up to 300 °C. The same behaviour is observed with the sample of Santa Catharina, which exhibits a non-Invar thermal behaviour of the lattice parameter (Fig. 3c₁). The Invar property returns when the sample is heated at 800 °C for 24 h in a non-oxidising atmosphere (Fig. 3c₂).

Fig. 2 001 row of the reciprocal space observed with a single crystal diffractometer using the $K\alpha$ Co filtered radiation: *a*, Fe-Ni Invar alloy before irradiation; *b*, Fe-Ni Invar alloy after irradiation; *c*, Santa Catharina meteorite.

ingly low cooling rate which prevails in meteorites when they are inside their parent bodies.

The extensive phase segregation and large proportion of ordered phase observed in the Santa Catharina meteorite are mainly due to its peculiar Ni content (35%), because, as we shall report elsewhere¹⁰, the Invar anomalies which affect both the taenite face centred cubic lattice parameters and the alloy elastic constants also critically affect the phase stability in Fe-Ni alloys.

J.D. thanks J. M. Knudsen for useful discussions.

Received 28 December 1979; accepted 13 February 1980.

These results show that the Fe-Ni phases in Santa Catharina exhibit the same properties of the irradiated Fe-Ni Invar alloy in which phase segregation and radiation-induced ordering occurs with the formation of the L10 superstructure. Basically, the radiation increases the kinetics of the phase segregation and ordering of the alloy. Essentially the same processes occur in the meteorite, but on a much different time scale due to the exceed-

Ammonia gas concentrations over the Southern Ocean

G. P. Ayers & J. L. Gras

Division of Cloud Physics, CSIRO, Sydney, Australia

Ammonia is the only common, soluble, basic gas in the atmosphere and as such plays an important neutralising, sometimes rate-determining, role in the chemistry of acid gases such as SO_2 , H_2SO_4 and HNO_3 . It also constitutes a reservoir of labile nitrogen in the atmosphere and so must be included in any attempt to describe the cycling of nitrogen through the global environment. We report here values of ammonia concentration measured in Southern Ocean air which are considerably lower than any previously reported¹⁻⁵. For our analyses ammonia was collected on oxalic acid-impregnated filters and determined colorimetrically. In air apparently devoid of contact with land for several thousands of kilometres of travel the mean concentration of ammonia gas was $0.06 \mu\text{g m}^{-3}$ (STP). Concentrations in air apparently affected by the Australian continent were several times higher than in the maritime air.

Measurements were carried out at the Australian Baseline Atmospheric Monitoring Station at Cape Grim (40.7°S , 144.7°E) on the northwestern tip of Tasmania. This is a coastal site at a latitude where only a few per cent of the Earth's perimeter is land and where shipping traffic is minimal. With no land for several thousands of kilometres in directions between 180° and 290° the station is ideally placed to sample the west-southwesterly winds of the roaring forties, which prevail for more than 60% of the time. There are frequent opportunities for sampling Southern Ocean air free from recent contact with land or human activities.

The method used for measuring the ammonia concentration is a simple but sensitive ring oven analytical technique⁶. Samples are collected over a period of 3 (or more) hours on oxalic acid-impregnated filters using a PTFE (Millipore Fluoropore) prefilter heated $\sim 20^\circ\text{C}$ above ambient. This system has been calibrated directly down to concentrations of $1 \mu\text{g m}^{-3}$ and found to be quantitative; particulate collection efficiency on the prefilter has been measured and is 100%. Evolution of ammonia from particles collected on the prefilter was tested by periodically inserting an oxalic acid-impregnated filter upstream of the prefilter. No evidence of significant volatilisation was found. Aitken nuclei were measured with an automated nucleus counter referenced to a faithful replica of the counter developed and calibrated by Pollak⁷.

Experiments were carried out between 1 and 14 August 1979. Conditions remained relatively constant throughout, with gently precipitating bands of cumulus cloud passing over the station at intervals of several hours. Temperature remained between 7.4 and 11.9°C . Wind direction was from the 'baseline sector' (180° to 290°) for 1-4 August and 9-14 August, and from the direction of the Australian mainland (290° - 55°) in the intervening period. Surface pressure charts for these three periods are shown in Fig. 1. Records of temperature, wind direction, Aitken nucleus concentration and ammonia gas concentration are displayed in Fig. 2.

The ammonia and Aitken nucleus concentrations seem to be well correlated, with both following closely the observed changes in wind direction. Figure 2 shows that, after allowing for the scatter in the ring oven results, the lowest values occur for winds from the baseline sector. As Aitken nucleus concentration is a sensitive tracer of continental sources in maritime regions, the most reasonable explanation for these variations is that during the period 5-8 August northerly winds brought continental air from the Australian mainland 250 km to the north, whereas the lower levels of ammonia and Aitken nuclei

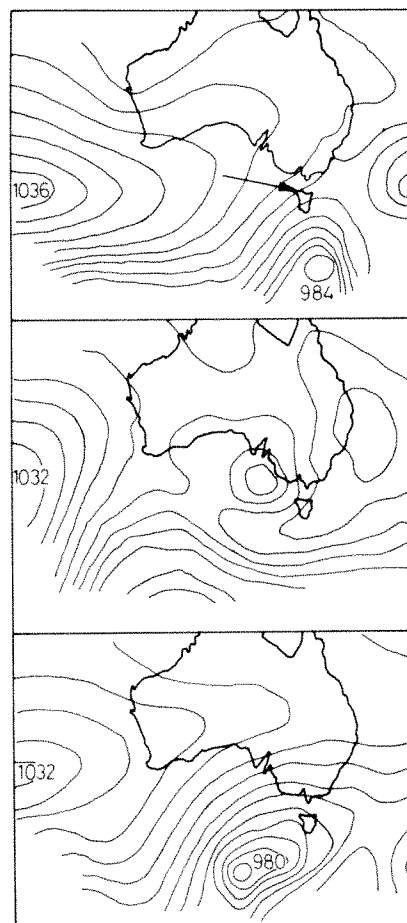

Fig. 1 09.00 EST surface pressure charts. Top, 1 August 1979; middle, 6 August 1979; bottom, 9 August 1979. Isobars are at 4-mbar intervals. The arrow shows Cape Grim.

during 2-4 and 9-14 August correspond with what was a relatively unpolluted southwesterly stream over the Southern Ocean. For 2-4 and 9-14 August we have 41 ammonia gas determinations, giving a mean of $0.06 \mu\text{g m}^{-3}$ (STP) and sample standard deviation of $0.03 \mu\text{g m}^{-3}$ (STP). This is significantly smaller than concentrations reported elsewhere: the range is typically 1 - $10 \mu\text{g m}^{-3}$ (STP) for the troposphere over Hawaii⁵, central Europe^{1,2}, and the Atlantic⁴ and Pacific Oceans³, with lowest values of $0.2 \mu\text{g m}^{-3}$ (STP)^{3,4}. Our values in the non-baseline condition average $0.18 \mu\text{g m}^{-3}$ (STP), with a sample standard deviation of $0.06 \mu\text{g m}^{-3}$ (STP).

Buch⁸ (in 1920) and others^{4,9} have pointed out that the concentration of ammonia near the ocean surface away from stronger sources (such as continents) should be determined by the composition of the surface waters by a Henry's law relationship. The Southern Ocean area is probably one of the few areas where very long air mass trajectories over the ocean enable this hypothesis to be tested. At present we have no knowledge of the distribution of dissolved ammonia in the ocean upwind of Cape Grim to compare with values predicted from our very low atmospheric concentrations. However, it is of interest to investigate whether the atmospheric values are consistent with the range of surface water ammonia concentrations reported from other locations and with those found in coastal water samples taken at Cape Grim.

From Lau and Charlson⁹

$$p\text{NH}_3 = \frac{K_H K_w [\text{NH}_4^+]}{K_b [\text{H}^+]} \quad (1)$$

where K_H is the Henry's law constant for ammonia, K_w the dissociation constant for water and K_b that for aqueous

Fig. 2 Records of dry bulb temperature, wind direction, Aitken nucleus concentration and ammonia gas concentration. All points except the ammonia concentrations are 4-hourly averages derived from 24 10-min integrations of the quantity being measured. In the case of ammonia two collectors were used in parallel, with results shown as sets of thick or thin bars. The length of each bar corresponds to the sampling period for that determination.

ammonia. Like Georgii and Gravenhorst⁴, we allow for the fact that the determination of dissolved ammonia does not distinguish between NH_3 and NH_4^+ , by letting

$$a = [\text{NH}_3] + [\text{NH}_4^+] \quad (2)$$

Substitution for $[\text{NH}_3]$ in the expression for K_b gives

$$[\text{NH}_4^+] = \frac{aK_b}{K_b + (K_w/[H^+])} \quad (3)$$

Putting equation (3) in equation (1) and rearranging gives

$$a = \frac{p\text{NH}_3\{K_w + K_b[H^+]\}}{K_H K_w} \quad (4)$$

Values of K_H , K_w and K_b and their temperature dependences are available elsewhere^{10,11}. In the present case we use values for 10 °C, the mean temperature during the experiments: $K_H = 8.26 \times 10^{-3} \text{ atm mol}^{-1} \text{ l}$; $K_w = 2.92 \times 10^{-15} \text{ mol}^2 \text{ l}^{-2}$; $K_b = 1.57 \times 10^{-5} \text{ mol l}^{-1}$.

For the measured ammonia gas concentration of $0.06 \mu\text{g m}^{-3}$ (STP) and coastal water pH of 8.2, equation (4) implies that, if equilibrium is established, the dissolved ammonia concentration is $0.3 \mu\text{mol l}^{-1}$. This falls within the range of dissolved ammonia values found in the literature, <0.05 to ~ 1 or $2 \mu\text{mol l}^{-1}$, with values from the open ocean lying towards the lower end of this range¹². Our own measurements on three separate samples of coastal water collected during the gas measurements yielded dissolved ammonia concentrations of 0.23, 0.30 and $0.55 \mu\text{mol l}^{-1}$. These results must be qualified, as the analyses were performed two weeks after collection; although the samples were stored untreated in polythene bottles at 0 °C and the pH was unchanged over this period it is well-known that storage can affect seawater samples for ammonia analysis¹³.

We therefore conclude that: (1) in winter levels of atmospheric ammonia in Southern Ocean air are 10–100 times less than those reported elsewhere; (2) there are indications that the

mean value observed, $0.06 \mu\text{g m}^{-3}$ (STP), results from a Henry's law equilibrium between atmospheric ammonia and that dissolved in the surface of the ocean.

Are warm-core eddies unproductive?

D. J. Tranter, R. R. Parker & G. R. Cresswell

CSIRO Division of Fisheries and Oceanography, PO Box 21, Cronulla, NSW 2230, Australia

Warm-core eddies¹ are large lenses of subtropical water (radius 100–150 km) wandering through a cooler sea. Figure 1 shows the path of one such eddy (eddy F) in the south-west Tasman Sea. Warm-core eddies in this area are shed by the East Australian Current (EAC)³. Because the EAC is fed mainly by central waters from the western South Pacific^{4,5}, it is low in surface nutrient and generally unproductive^{6,7}. The eddies which it sheds might, therefore, be expected to be equally unproductive. However, the phytoplankton concentration in eddy F increased about fivefold between September⁸ and November 1978⁷. This 'anomaly' is considered here.

Warm-core eddies in the south-west Tasman Sea are recognised by their isothermal layer which extends at the eddy centre

Fig. 1 Probable track of eddy F as deduced from XBT profiles and daily fixes on satellite-tracked buoys drogued at 20 m (ref. 2) (NASA MET SAT NIMBUS-6). Buoy no. 1054 entered the eddy at ① on 16 September and made six complete anticlockwise circuits within the eddy (solid lines) before a systems interruption on 19 October ②. Buoy no. 1132 was released at ③ on 10 October and made two circuits (dashed line) by 19 October ④. The eddy itself seemed to have followed an anticlockwise arc of half a revolution between mid-September and mid-November ⑤.

Fig. 2 Temperature profiles taken inside (solid lines) and outside the eddy (dotted lines) in September and November 1978. The eddy is characterised by a deep isothermal layer (IL). In November this was overlain by a slightly warmer 'cap' (c).

to depths as great as 300 m (Fig. 2). A convenient way of identifying particular eddies, and tracking them as they move about, is by their temperature at a depth of 250 m (T_{250}). The centre of eddy F had a T_{250} of 17.5–17.7°C. The T_{250} at the perimeter of the eddy was ~15°C. In the following comparison, locations of $T_{250} > 17^\circ\text{C}$ are regarded as lying near the centre of the eddy and those at $T_{250} < 15^\circ\text{C}$ as lying outside the eddy boundary.

In September 1978 (late winter) the phytoplankton concentration was lower inside the eddy than it was outside (Fig. 3). A second eddy further west (eddy E) had a similar pattern. In November (early summer), the situation was reversed; eddy F now seemed to be far more productive than it had been 2 months earlier (Table 1). The added phytoplankton must either have been brought in from outside the eddy or produced *in situ* from the eddy's own nutrient reserves.

This is undoubtedly the same eddy that was previously under observation in September. Its unique signature is the 17.5–17.7°C isothermal layer (Fig. 2), and its trajectory had been tracked continuously by 'satellite-buoys' drogued at 20 m: buoys drogued at this depth are relatively unaffected by prevailing winds². The most obvious physical change that had taken

Table 1 Comparison of waters inside and outside eddy F during September and November 1978

Month (1978)	T_{250} (°C)	T_0 (°C)	Parameter DML (m)	NO_3 ($\mu\text{mol N l}^{-1}$)	F_M (TU)
September					
Inside	>17	17.7	215–320	2.9–3.2	100–200
Outside	<15	15.3–20.2	37–88	1.1–3.3	200
November					
Inside	>17	18.0–18.2	60–65	0.3–0.8	200–600
Outside	<15	17.5–18.2	60	0.6	200–400

Depth of the mixed layer (DML), T_{250} and T_0 were taken from XBT records. Nitrate was determined by the strychnidine method⁹ using Nansen bottle samples; the values shown are averages for the mixed layer. F_M (*in vivo* chlorophyll *a* fluorescence maximised with 'Diuron'^{10,11}) was measured in a flow-through system with injected dose to give 6 μM concentrations. The source water was pumped through the ship's hull from ~2 m depth. F_M is given in standardised *in vivo* chlorophyll *a* fluorescence units¹² (TU) and is taken as an index of phytoplankton biomass.

place in the interim was the development of a warmer 'cap' (18.0–18.2°C) extending to a depth of 60–65 m (Table 1). The depth of mixing had changed from >300 m (the depth of the deep isothermal layer) to <100 m (the depth of the surface cap). Did this cap develop *in situ* by surface warming, or was it derived from 'outside' surface water which had washed across the top of the eddy?

We first consider the possibility of advection. The EAC tends to advance southwards in the summer, sometimes 'recapturing' eddies shed the previous winter, particularly those located north of Sydney (C. J. Nilsson and G.R.C., unpublished data). However, in November 1978, the EAC was located 640 km north of eddy F. Had warm water from another source washed across the top of eddy F we would have expected the buoys adrift within the eddy (Fig. 1) to be ejected: they were not. Phytoplankton concentrations immediately north of eddy F were much too low to represent a likely source of advected water (Fig. 3). Only beyond its southern limits were November phytoplankton concentrations of the same order as those within the eddy, and here the water was too cold to be a likely source.

For these reasons, we have concluded that the development of the summer cap in eddy F, and the associated increase in phytoplankton concentration, were processes that took place *in situ*, within the confines of the eddy. How did they take place?

Data presented in Table 1 provide a contrast between the conditions prevailing in September and November, both for eddy F and the surrounding waters. The focus is on winter mixing and thermocline formation. In the eddy, winter mixing

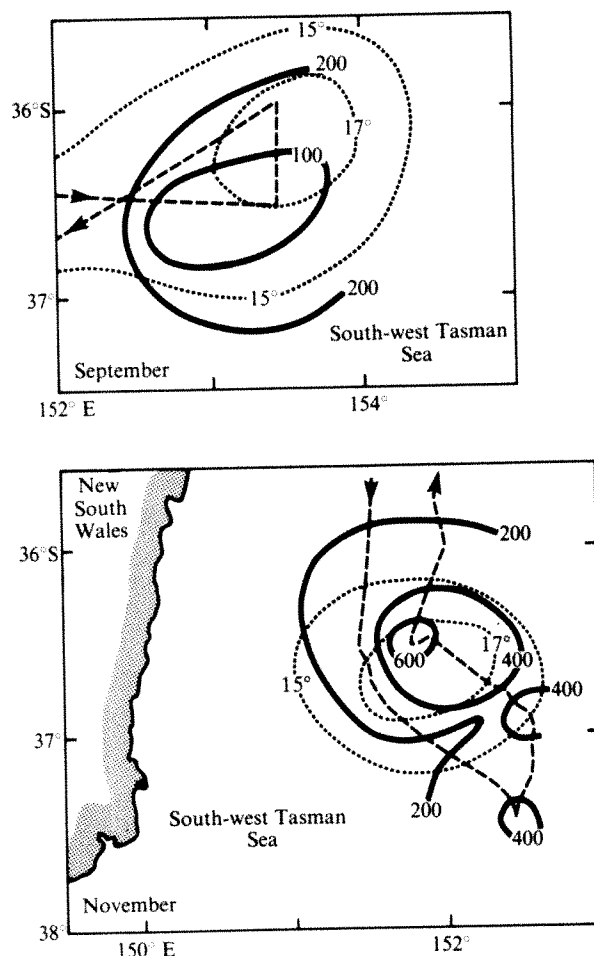

Fig. 3 'Surface' phytoplankton concentration in the region of eddy F in September and November 1978. The perimeter of the eddy is indicated by the 15°C isotherm (at 250 m), the centre by the 17°C isotherm. The phytoplankton contours are *in vivo* chlorophyll *a* fluorescence (F_M) measured underway along the cruise track (for details see Table 1).

had extended deeper, distributing inorganic nitrate fairly uniformly throughout the isothermal layer (Fig. 4). In September, deep-lying stores of NO_3 were being mixed into the euphotic zone of the eddy. By November, most of that which had been introduced in this way was now present in the form of phytoplankton biomass. The mean NO_3 concentration in the upper mixed layer of the eddy (60–65 m) had decreased from 2.9–3.2 $\mu\text{mol N l}^{-1}$ in September, to 0.3–0.8 $\mu\text{mol N l}^{-1}$ in November. The September and November status of eddy F are described in detail elsewhere^{7,8}, as are the conditions in October and December^{13,14}.

Fig. 4 Nitrate (NO_3) profiles for stations inside the eddy in September and November. September profiles in the eddy displayed nitrate concentrations of the order of 3 $\mu\text{mol N l}^{-1}$ to 200 m. The November profile indicated that more than half of this had been consumed.

These phenomena are explained by Sverdrup's model¹⁵ of environmental control of the spring bloom¹⁶. The Sverdrup model explains the onset of a bloom in relation to the depth of the mixed layer and to the 'critical depth', that is, where respiration losses for the water column equal gains by photosynthesis. In the south-west Tasman Sea, the 1% light level is at a depth of about 75 m (ref. 17), much shallower than the depth to which eddy F mixed in September (250–350 m). Consequently, the standing crop could not increase. Nutrients were distributed throughout the mixed layer, but remained unused for plant production during this light-limited mixing era. When in contact with a mass of air cooler than that at its origin, the eddy took longer to come to thermal equilibrium than did the surrounding sea. Its surface water continued to cool and sink to the level of the permanent thermocline. This process of convective overturn¹ caused deep mixing which persisted through the spring, by which time surface waters outside the eddy had begun to warm. By November, the eddy mixing cycle had ended and it had developed a summer cap (Fig. 2).

We conclude, therefore, that the production of a warm-core eddy is greater than that of the water mass from which it is derived because prolonged surface cooling and deep convective mixing convey previously unavailable nutrients to the surface. This results from the movement of the eddy into a location where the atmosphere is significantly colder.

When eddies are isolated from the surrounding sea, their production is limited by the concentration of nutrients in the winter isothermal layer. Each subsequent year this would be reduced by annual phytoplankton blooms, much of which material would presumably be lost to the system by detrital fallout. In addition to this organic loss, the eddy would lose heat and eventually come to equilibrium with atmosphere and surrounding sea. We would expect these two factors to combine to reduce progressively the scale of consecutive phytoplankton blooms for as long as the eddy remained a discrete water body.

Our studies^{7,8,13,14} show that warm-core eddies can be useful systems in which to study pelagic processes. They can readily be

identified, marked and tracked through time, and are sometimes so discrete that a pulse of primary production can be followed through the food chain.

This letter has dealt principally with production in the eddy proper. Unpublished information indicates that plankton are concentrated at the frontal boundary of the eddy. The factors controlling these concentrations are being studied.

A revised age for the Donegal granites

A. N. Halliday & M. Aftalion

Scottish Universities Research and Reactor Centre, East Kilbride, Glasgow G75 0QU, UK

B. E. Leake

Department of Geology, The University, Glasgow G12 8QQ, UK

The Donegal granites in north-west Ireland are among the best mapped granitic intrusions in the world¹. They form part of a broad suite of granites intruded during the Palaeozoic but within a relatively small area encompass a wide range of emplacement features. A published Rb–Sr composite whole rock isochron for these granites defined a date of 487 ± 5 Myr (refs 2, 3) whereas K–Ar ages exhibited a spread from 365 ± 8 to 412 ± 8 Myr (refs 1, 4). (All age data are normalized to recently recommended decay constants⁵). Although some doubt was cast on the older Rb–Sr date by Pitcher and Berger (ref. 1, p. 90) and Leake⁶ it has generally been accepted as a more valid estimate of the emplacement age^{2,3,7–9}. Here we summarize the results of Rb–Sr and U–Pb isotopic analyses recently carried out which indicate that the Rosses, Ardara, Trawenagh Bay and Main Donegal intrusions were, in fact, all emplaced close to 400 Myr ago.

Rb–Sr isotopic analyses have been made on more than 70 whole rocks (5–10 kg size) and mineral separates and U–Pb isotopic analyses on zircons and a monazite using methods outlined elsewhere¹⁰. The complete results together with their petrogenetic implications will be presented elsewhere. Here we present a summary of the regression results¹¹ obtained on Rb–Sr age data for those portions of each of four of the main intrusions which best define perfect isochrons. The sum of the squares of the residuals (SUMS) indicates the goodness of fit of the data relative to that expected from the analytical uncertainties. For the Ardara, Rosses and Trawenagh Bay intrusions the best fitting data come from the central portions of the intrusions and the aplites which exhibit a wider spread of Rb/Sr ratio. The outer portions of these intrusions (for which results are not

shown) apparently have variable initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios (compare with refs 12–14). Samples from the Main Donegal Granite had a restricted range of Rb/Sr and the results obtained from mineral separates and the corresponding whole rock samples are given.

The Rosses Complex whole rock data yield a well defined isochron age of 404 ± 3 Myr which is effectively identical to the age of 405 ± 3 Myr obtained for Trawenagh Bay intrusion (Fig. 1, Table 1). The Ardara data scatter significantly at the 5% level and the best fitting age of 405 Myr should be regarded as an approximation to the age of intrusion. Use of York's¹¹ "scatter error" would give a 2σ uncertainty of ± 15 Myr. The five mineral separates (biotite, muscovite, K-feldspar, plagioclase and apatite) and whole rock data points for sample D/12/4 of the Main Granite define an isochron date of 388 ± 3 Myr. This probably represents the time when the intrusion cooled. A second sample (D/17/1) gives similar results for muscovite–biotite–apatite–whole rock, but K-feldspar and plagioclase scatter slightly away from the other points.

A U–Pb isotopic analysis of monazite from the Trawenagh Bay pluton yielded concordant $^{238}\text{U}/^{206}\text{Pb}$, $^{235}\text{U}/^{207}\text{Pb}$ and $^{207}\text{Pb}/^{206}\text{Pb}$ ages whose mean is 411 ± 2 Myr (2σ). U–Pb data for zircons, however, are all discordant with marked inherited radiogenic Pb components analogous to many Caledonian granites from Scotland, north of the Highland Boundary Fault¹⁵. These data strongly suggest melting or assimilation of Precambrian crustal materials or their sedimentary or magmatic derivatives in the genesis of the granites. In this respect it is of interest that the initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of the magmas were low (Table 1) which further restricts the sources to having low Rb/Sr ratios. Hence the Donegal granites were generated from low Rb/Sr, low $^{87}\text{Sr}/^{86}\text{Sr}$ crust, possibly in combination with mantle or basaltic lower crustal materials (compare with ref. 10 and ref. 1, Ch. 16).

Pitcher and Berger (ref. 1, p. 90) outlined the probable chronology of these Donegal granites in the order Ardara, Rosses, Main Granite and Trawenagh Bay. The best age data here have been obtained on the Rosses and Trawenagh Bay intrusions which yield similar Rb–Sr whole rock dates indicating that it is exceedingly unlikely that the former preceded the latter by more than 5 Myr. The slight difference between the U–Pb monazite date and the Rb–Sr whole rock date for Trawenagh Bay could merely reflect the uncertainty of absolute calibration of each dating system. The minerals-whole rock Rb–Sr age of 388 ± 3 Myr obtained from the Main Donegal Granite places a minimum on the emplacement age of this intrusion. The highly foliated character of this granite makes it clear that mineral dates should be interpreted with caution. The results from

Fig. 1 Rb–Sr isochron diagram for Trawenagh Bay (aplitic phase) and Rosses (G3, G4 and aplites) whole rock samples, and biotites and muscovites from the Main Donegal granite. Reference isochrons are shown.

Ardara indicate that this intrusion was emplaced at about the same time as the others.

The results presented here are inconsistent with previous Rb–Sr age studies^{2,3} in which the Rb–Sr data were interpreted as indicating an age of 487 ± 5 Myr for the Main Donegal, Trawenagh Bay, Thor and Rosses granites, and also inconsistent with a time lapse of ~ 40 Myr between intrusion of the Rosses granite and its aplites². Our results are not inconsistent with those of Long¹⁶ but do resolve the ages more satisfactorily and indicate that the whole rock Rb–Sr isochron date of 352 ± 16 Myr (decay constant not given) he obtained for the Main Donegal Granite does not reflect the emplacement age.

The results presented here indicate that at least a major portion of the magmatism in Donegal took place close to 400 Myr ago and that these granites are temporally related to the 'newer' and 'last' Granites as defined by Read¹⁷. Several implications follow from this. The major deformation and metamorphism in Donegal could be younger than previously thought³, and there is no need to invoke diachronous deformation between County Mayo and County Donegal on the basis of the radiometric age of the Donegal granites^{7,9}. Similarly the need to fit voluminous but localized intrusions of granite at ~ 490 Myr into plate tectonic models of the Caledonides^{7,8} can be done away with. Like most Caledonian granite magmatism the Donegal granites seem to relate temporally to late- or post-closure processes.

The Isotope Geology Unit at SURRC is supported by NERC and the Scottish Universities. We thank J. Hutchinson and J. Jocelyn for technical assistance and W. S. Pitcher, A. R. Berger and D. H. W. Hutton for discussions.

The connectance of real ecosystems

Peter Yodzis

Department of Zoology, University of Guelph, Guelph, Ontario, Canada N1G 2W1

In the work of Gardner and Ashby¹, and May² it has been shown that ecosystem stability (in the sense of Liapunov stability of equilibria³) imposes nontrivial constraints (summarised below) on ecosystem structure, but little has been done to relate this work to observations. One such study was undertaken by Rejmánek and Stárý⁴, who found in a collection of plant-aphid-parasitoid food webs that connectance C (roughly speaking, the fraction of pairs of species that directly interact) decreases like S^{-1} as species richness S (the total number of species) increases. Here I analyse a sample of community food webs (the webs of ref. 4 are sink webs⁵), and find a somewhat slower decrease of connectance with increasing species richness. This behaviour suggests, within the context of May's theory², that complex ecosystems will tend either to be more fragile or to have weaker interspecific interactions than simpler ones.

Connectance, as it occurs in May's theory, is defined precisely as the fraction of non-zero off-diagonal elements of the community matrix². One can also define⁶ an 'average strength', i , of interspecies interactions. Then, for a certain ensemble of randomly constructed systems, May found that the community matrix will almost certainly be stable if

$$i < (SC)^{-1/2} \quad (1)$$

and it will almost certainly be unstable if

$$i > (SC)^{-1/2} \quad (2)$$

with the transition from stability to instability being very sharp if $S \gg 1$.

A food web, which specifies the feeding relationships in a community, can be used to estimate the connectance of the community matrix as follows. First, if species a feeds on species b then the elements A_{ab} and A_{ba} of the community matrix A will certainly be non-zero. If we know all the feeding relationships in a community, we can determine in this way a set of community matrix elements which are certainly non-zero, whence a lower bound C_1 on the connectance. Second, some species will directly interfere with one another, generally in competition for shared

Fig. 1 The estimates C_1 (circles) and C_u (squares), plotted against species richness S for the 24 community food web versions compiled by Cohen⁵. Each open symbol corresponds to two food web versions.

resources. Thus if species a feeds on species b and species c also feeds on species b , then species a and c may engage in interference competition with one another (although they may instead manage to avoid such competition by, for instance, partitioning the food resource in some way). If these two species do interfere with one another, then the elements A_{ac} and A_{ca} will be non-zero. Assuming that any two species which share any food resource interfere with one another, we can determine in this way an additional set of potentially non-zero community matrix elements which, added to the feeding matrix elements previously obtained, yield another estimate C_u of the connectance.

In general there will be additional interactions in a community, due to, for instance, competition for resources other than food, parasitism, and mutualism. If we assume that these interactions are less common than interactions involving food resources, then C_u can be regarded as something like an upper bound on connectance. Otherwise, it can simply be regarded as an estimate which is arrived at in a well-defined way.

Fig. 2 The estimates $(SC_1)^{-1/2}$ (circles) and $(SC_u)^{-1/2}$ (squares), plotted against species richness S for the 24 community food web versions compiled by Cohen⁵. Each open symbol corresponds to two food web versions. The straight lines are linear regressions of $(SC_1)^{-1/2}$ and $(SC_u)^{-1/2}$ on S .

Cohen⁵ has extracted 24 community food web versions from literature data. While admittedly far from perfect (especially with regard to grouping species into categories), this collection is probably the best statistical base presently available for food web studies. In several cases Cohen gives two (or even three) food web versions for one community; thus one can distinguish for some communities between food web versions of type A, which include only feeding relationships of which the field investigator was certain, and food web versions of type B, which include additional feeding relationships considered probable by the observer. It is not entirely clear whether the most sensible statistical sample is the full collection of all 24 food web versions, the set of 14 type A food web versions, or the set of 14 type B food web versions. Fortunately, the results of this investigation are essentially the same for all three samples.

The connectance estimates C_1 and C_u for Cohen's 24 community food web versions are plotted against species richness S in Fig. 1. There is a clearly discernible tendency for both estimates to decrease as S increases. However, for decreasing connectance alone to account for the stability of complex systems, C must decrease at least as fast as S^{-1} , which is not the case here.

This is made explicit in Fig. 2, which is a plot of the two estimates for $(SC)^{-1/2}$ (hence, according to equation (1), the upper bound on the interaction strength i which allows stability) against S for the 24 Cohen community food web versions. The straight lines are linear regressions on S of the two estimates;

Fig. 3 The number of dominant cliques plotted against species richness S for the 24 community food web versions compiled by Cohen⁵.

both slopes are negative and significantly different from zero (Student's t -test, $P = 0.0036$ for $(SC_1)^{-1/2}$, $P = 0.0006$ for $(SC_u)^{-1/2}$). The significance of this, at least within May's framework², is that unless average interaction strength tends to decrease with increasing S , systems with larger S will be closer to the critical value $i(SC)^{1/2} = 1$ which marks the transition to instability; one expects that such systems would be more fragile in the sense of susceptibility to external perturbations.

Most ecologists would probably expect a decrease in C as S increases, on the basis that ecosystems tend to be organised into

relatively small 'guilds' of species, with most interactions taking place within guilds^{2,6-9}. This idea can be made precise and tested as follows. Define a 'clique' as a set of species with the property that every pair of species in the set has some food resource in common, and define a dominant clique as a clique which is contained in no other clique^{5,10}. These dominant cliques may appropriately be regarded as 'guilds'. In Fig. 3 the number of dominant cliques is plotted against species richness S for the 24 Cohen community web versions. The number of dominant cliques increases with S , although perhaps not as rapidly as one might have expected.

This work was carried out at the Institut für Theoretische Physik der Universität Bern, Switzerland. I thank my friends and colleagues in Bern for their support.

Effects of leaf age and plant life history patterns on herbivory

Phyllis D. Coley

Committee on Evolutionary Biology, University of Chicago, Chicago, Illinois 60637

Current theories on plant-herbivore interactions suggest that plant species of different successional status and leaves of various ages differ in their degree of ephemerality and predictability to herbivores, and will therefore exhibit different anti-herbivore characteristics¹⁻⁶. Old leaves and leaves of mature forest plants are expected to be better defended than ephemeral young leaves and leaves of early successional plants. These predicted patterns of plant defence and the resultant patterns of insect grazing are not well documented for natural communities. Field studies have shown that mammalian herbivores in a tropical forest prefer young leaves⁷ and that insect grazing in a temperate forest is heaviest on the young leaves⁸. Laboratory studies have shown that late successional species⁹⁻¹² or plants with certain chemical defences¹³⁻¹⁷ are less palatable for generalist herbivores. Laboratory results depend, however, on the particular herbivore tested, and may not accurately predict rates of herbivory in natural systems. Here I report on rates of herbivory on young and mature leaves from tree species with different life history patterns. Grazing rates (% leaf area eaten per day) on mature leaves of fast growing, shade-intolerant species (pioneers) were an order of magnitude greater than those on slow growing, shade-tolerant species (persistents). Young leaves in both groups of species suffered significantly greater grazing damage than mature leaves.

For this study, tree species were classified into two groups, pioneers or persistents. Persistent species tolerate shade as seedlings and saplings, whereas pioneer species are unable to survive in the shade¹⁸⁻²³. Pioneer species may differ from persistent ones in antiherbivore characteristics because of these differences in their life history patterns. Persistent species grow slowly for long periods of time in the understory before a light gap opens above them, and thus they may be a more predictable resource for herbivores and may be expected to possess costly and effective defences. Mature leaves may be tough and contain

substances that reduce digestibility, such as tannins and resins^{1-4,24,25}. In contrast, saplings of pioneer species may invest in metabolically less expensive toxic chemicals and instead rely primarily on escaping herbivory through fast growth and a patchy occurrence in light gaps¹⁻⁴. Young expanding leaves of both types of plants are a nutritious^{5,26,27} and ephemeral resource, and presumably are not heavily defended by chemicals, especially not substances that reduce digestibility (refs 1-6 but see 7, 28). Synchronous flushing of young leaves by individuals or populations could lead to temporal escape as well as satiation of herbivores^{5,29,30}.

Rates of insect grazing were evaluated for 235 saplings (1-2 m high) of 11 pioneer and 16 persistent species growing in 13 light gaps in the semideciduous forest of Barro Colorado Island, Panama³¹. These 27 species of canopy trees were chosen because both adults and saplings were abundant. I measured total leaf area and area of holes made by herbivores of 1,745 marked young and old leaves at 2-week intervals for three months at the beginning of the rainy season (April-July 1977). Young leaves were measured from the time they emerged from the bud until they were fully expanded and had mature characteristics. Grazing rates were expressed as the percentage of the entire leaf area eaten per day which controls for leaf area in expanding young leaves (see Table 1 for a description of rate measures).

The data on grazing rates (Table 1) suggest that there is a strong relationship of both life history patterns and leaf age with grazing by herbivores. For 23 of the 27 species, there is no overlap between the distributions of pioneer and persistent species in the mean grazing values on mature leaves. There is an order of magnitude difference between the mean grazing rate on mature persistent leaves and that on either mature leaves of pioneers or young leaves of persistents. There is a smaller but significant difference ($P < 0.01$) between the grazing rates on young and mature pioneer leaves. There is no significant difference between the grazing rates on young leaves of pioneer and persistent species.

These results support predictions of current hypotheses¹⁻⁴ which propose that investment in antiherbivore defences will reflect the degree of predictability of each plant or plant part as a resource for herbivores. Low rates of grazing on mature persistent leaves suggest that they are well defended from herbivores, possibly by digestibility reducing substances³. High rates of herbivory on young leaves and pioneer plants suggest that if escape in time or space is operating, it is apparently not so

Grazing rates for each leaf were computed as $100 \times (\text{change in hole area}) / ((\text{total leaf area}) \times (\text{no. of days between observations}))$. Significant distortion in the percentage of leaf area eaten does not occur during leaf expansion. Holes of known diameter were punched in 209 young leaves of five pioneer species (*Cecropia insignis*, *Croton bilbergianus*, *Miconia argentea*, *Trema micrantha* and *Zanthoxylum belizense*) and five persistent species (*Desmopsis panamensis*, *Protium tenuifolium*, *Trichilia cipo*, *Virola sebifera* and *Zanthoxylum panamense*). A regression of the percentage change in hole area against the percentage change in total leaf area over time gave a slope not significantly different from 1 ($P < 0.05$, $r^2 = 0.88$ around $\beta = 1$).

*Species are ordered by grazing rates on mature leaves.

†Values followed by the same letter are significantly different, $P < 0.01$ for a and $P < 0.001$ for b and c . Significance levels were determined by a nested 2-way ANOVA considering leaves as replicates on a transformation of the data: $\ln(1,000 \times \text{rate} + 1)$. Although the data were not normally distributed (as a result of many zero values), ANOVA seemed the most appropriate statistical method. The results were not changed when leaves with values of zero damage were excluded. Similar results were obtained when a new rate was calculated by averaging the actual leaf and hole areas per plant rather than the percentage eaten. This second rate of herbivory was computed as: $((\sum_i \text{change in hole area}) \times n_i) / ((\sum_i \text{leaf area}) \times (\sum_i \text{no. of observation days}))$, where i is the i th plant and n the number of leaves. This measure of grazing is less sensitive to the contribution by young leaves that were completely eaten.

‡Standard error of the species means.

effective in reducing losses to herbivores. The magnitude of the differences in grazing rates that I observed emphasises the range of susceptibility to herbivores that exists in natural communities and the presumed variety and effectiveness of different anti-herbivore characteristics.

Female mimicry in male bluegill sunfish—a genetic polymorphism?

Wallace J. Dominey

Field of Neurobiology and Behavior, Cornell University, Ithaca, New York 14850

When male reproductive success depends on male-male competition and aggression, individuals which are at a competitive disadvantage sometimes adopt an entirely different constellation of reproductive behaviours. When such alternative reproductive patterns are practised opportunistically, as when a defeated territorial male adopts a parasitic role, or as part of a developmental sequence, as when younger males are satellites, they can be considered to be part of a single lifetime reproductive strategy. In contrast, when alternatives are available but individuals practise only a single reproductive option throughout their lifetime, the possibility of a genetic polymorphism can be considered. Such genetically mediated alternative reproductive strategies have been hypothesised¹, but the ontogeny of supposed alternative reproductive strategies is seldom known². This letter describes two reproductive patterns in bluegill sunfish (*Lepomis macrochirus*), a nesting male strategy and a female mimic strategy, and demonstrates that an individual male does not practise both reproductive strategies.

Alternative reproductive patterns have been described as 'sneak', 'satellite', or 'parasitic' behaviour, and have been found in a wide variety of taxonomic groups. These alternative patterns are often 'submissive', and can include the display of female characteristics which serve to reduce male aggression³⁻⁵. The most detailed cases of female mimicry as a reproductive option have been reported in scorpionflies⁶, where males increase their frequency of mating by obtaining nuptial gifts from other males; salamanders⁷, where males stimulate rivals to waste their gametes; and fishes, where female mimics attempt to gain access to females attracted to territorial males. In these cases of detailed female mimicry, individuals either were not identified or were observed to practise both typical male behaviour and female mimicry.

For fishes, female mimicry was first described in the 10-spined stickleback, *Pungitius pungitius* L.⁸, and the leaf fish *Polycentrus schomburgkii*⁹, in aquaria. Female mimics have recently been observed in the field in a Michigan population of *Lepomis macrochirus*¹⁰, and in benthic Mediterranean fishes of the genus *Tripterygion*¹¹. The behavioural observations reported here were made while snorkelling or scuba diving in Lake Cazenovia, New York, during the summers of 1976, 1978 and 1979, as part of a long-term study of the mating system of *Lepomis macrochirus*. Following all behavioural observations, individuals were captured with a hand net and stripped of their gonadal products to verify their sex. Because of the difficulty of identifying female mimics in the field, female mimicry in fishes may be much more common than the few reported instances indicate.

Fig. 1 Nesting male (left), female (right, depositing eggs), and female mimic (small dark fish, between) simultaneously spawning. The line drawing shows the position of the fish—the female mimic is almost lost in the shadow from the larger nesting male.

Fig. 2 Age distributions for female mimics (top) and nesting males (bottom).

As is typical of the species, male *Lepomis macrochirus* in Lake Cazenovia occupy nesting territories in densely packed colonies which may contain several hundred nests. Males compete aggressively for position within these colonies, and the ability of a male to maintain residency on a nest is related to its size (unpublished data). This is consistent with aquarium studies of *Lepomis macrochirus* and other sunfishes where body size has been found to be an important determinant of success in agonistic encounters¹²⁻¹⁵. Males which mimicked female behaviour in 1978 (\bar{x} = 126 mm, s.d. = 9 mm, n = 20) were much smaller than nesting males (\bar{x} = 190 mm, s.d. = 13 mm, n = 45), and were never seen to compete aggressively with them. Although the size distribution of female mimics was disjunct from that of nesting males, it did overlap with the lower end of the distribution for spawning females (\bar{x} = 156 mm, s.d. = 19 mm, n = 45).

An actively spawning *Lepomis macrochirus* colony is easily recognised because hundreds of females and males without nests typically aggregate in the water column. To initiate courtship, a female leaves this aggregation and swims towards a nesting male while displaying a coloration pattern (dark background, dark eyes, and pronounced vertical barring) known to reduce aggression in the nesting males of another sunfish, *Lepomis gibbosus*¹⁶. Once the female is in the nest, the male begins to swim in tight circles, turning, with the female following. Every few seconds as the pair turns, the female lies on her side, presses her genital pore against that of the male, quivers, and releases eggs that the male simultaneously fertilises¹⁷.

The behaviour of female mimics is essentially the same as that of functional females. Female mimics do not attempt to construct or defend nest sites, are found in the predominantly female aggregations, and solicit nesting males for courtship. These small males approach the aggressive, territorial males without hesitating or retreating, adopt the dark, barred coloration, and turn in the nest with the resident males. Surprisingly, in some colonies the majority of 'spawning' pairs were nesting male-female mimic pairs. Although this type of 'homosexual' behaviour would not seem to be immediately adaptive, the adaptive significance of female mimicry becomes evident when female mimics spawn as part of a trio (Fig. 1) or larger group which includes a functional female. During these spawning bouts, any eggs fertilised by female mimics are abandoned to the care of the nesting males.

As in the primary males of the bluehead wrasse *Thalassoma bifasciatum*, where sperm competition is also likely to be important¹⁸, the testes of female mimic *Lepomis macrochirus* occupy a greater proportion of their body weight (4.2%) than do the testes of territorial males (1.9%). These large, sperm-laden testes contrast strongly with immature testes or the atrophied testes found in non-breeding individuals. Although released sperm were not visible for either female mimics or nesting males during spawning bouts, a slight pressure to the abdomen of a

female mimic would invariably release copious quantities (compared with a nesting male) of sperm. In the laboratory, these sperm were found to fertilise eggs as readily as those of nesting males. Given that large amounts of active, fertile sperm are present and easily released mechanically, it is likely that during spawning bouts female mimics were releasing sperm and were fertilising eggs. An extremely complex and unusual evolutionary scenario would be required to explain why individuals with exceptionally developed and spermatogenically active testes would adopt an elaborate reproductive pattern, gain access to egg-releasing females, and then fail to release sperm.

Although female mimics are much too small to successfully practise nesting male behaviour during a given breeding season, these small males might continue to grow and eventually reach nesting male size. In such a case, where female mimics represented a developmental stage of nesting males, female mimics should show a younger age distribution. Fortunately, fishes, especially temperate, freshwater fishes offer a distinct advantage over many other vertebrates for studies of the ontogeny of alternative reproductive strategies because they can be accurately aged using the growth characteristics of their otoliths¹⁹. The otoliths of Lake Cazenovia *Lepomis macrochirus* proved to be easily read and unambiguous as to age.

One advantage of using otoliths rather than the more commonly used scales is that with otoliths the annual rings (annuli) can be verified using daily changes in otolith microstructure²⁰. For both female mimics and nesting males, the annuli for the first years of life showed the appropriate number of daily growth increments (E. B. Brothers, personal communication). Although daily increments are more difficult to discern late in life (because of the slowness of growth), the pattern of growth and the appearance of the annuli were unchanged for later years. Daily increments in otolith microstructure have been shown to correspond to daily growth in laboratory reared sunfishes (including *Lepomis macrochirus*), and rings which resembled the annuli of wild caught fish have been induced in laboratory reared *Lepomis cyanellus* by appropriate 'seasonal' temperature manipulations²¹.

Including random population samples, nearly 2,000 fish were aged using otoliths. All otoliths were pooled and read twice, blind with respect to the age, sex and behavioural characteristics of the individual. Using this procedure, female mimics and nesting males were found to show similar age distributions (Fig. 2). Thus female mimics do not represent a normal developmental stage of nesting males. The slightly older age distribution of the nesting males probably results from competition among the males for nesting sites favouring older, larger individuals. Further evidence that female mimics do not mature into nesting males comes from the back-calculated growth rates of the nesting males. If any female mimics were to drastically increase their growth rate and reach nesting male size, the otoliths of some nesting males should show an increase in growth rate late in life. No nesting males showed such a growth increase.

Were alternative behaviour patterns such that individuals could 'switch' from one pattern to another (perhaps better termed 'tactic'), either opportunistically or as a part of development, the genetic substrate for both patterns would be present in every individual. Balancing the relative frequencies of occurrence for these types of alternative patterns is analogous to achieving an optimal mix for the expression of several courtship signals. Each courtship signal need not contribute equally to fitness to be expressed. Demonstrating that female mimics do not exhibit nesting male behaviour, either within a single breeding season or during the course of their ontogeny, however, raises the question of whether this is an example of a genetically maintained, balanced behavioural dimorphism. The next obvious step is to examine the relative contribution of the environment and of the genes to the observed phenotypes.

This research was supported by a doctoral dissertation improvement grant from the NSF, and by grants from the Ithaca and National chapters of Sigma Xi, the George D. Harris

Foundation, and the Theodore Roosevelt Memorial Fund of the American Museum of Natural History. E. B. Brothers, R. E. Burskirk, S. T. Emlen, G. Hausfater, J. B. Heiser and H. C. Howland gave comments on the manuscript. Use of the Cazenovia College Lake Station was granted by Don Roy, Director. E. B. Brothers suggested the use of otoliths and helped with the technique. A. Donjacour, A. Horn, S. Letovsky, C. Mercaldi, A. Plassman, C. Van Buren and J. Weiskotten served as field assistants.

At high speeds dolphins save energy by leaping

D. Au & D. Weihs*

NOAA National Marine Fisheries Service, Southwest Fisheries Center, La Jolla, California 92038

An observer may wonder whether a school of 'running' dolphins, consisting of numerous, wildly splashing individuals, is using the most efficient mode of locomotion, because splashing wastes energy. Dolphins exhibit at least three modes of swimming. In leisurely, unhurried motion, they break the surface briefly and gently, often showing little more than the blowhole. At a faster, 'cruising' speed, frequently at 3-3.5 ms⁻¹ (6-7 knots), the animals are seen swimming primarily just beneath the surface, and there is still little splashing. (Behaviour and speeds of dolphin schools were observed from a helicopter and will be described elsewhere by D. A. and W. Perryman.) Swimming speeds in this mode have been measured up to 4.6 ms⁻¹ (9.3 knots). But in the fastest 'running' mode, the animals clear the water in sequential, parabolic leaps, accompanied by considerable splashing on exit and re-entry (Fig. 1). Leaps are interspersed with relatively brief, subsurface swimming. This swimming is common when dolphins are alarmed by vessels approaching within 500 m. We have examined dolphin swimming in terms of energy required per unit distance travelled and report here that beyond a certain 'crossover' speed, leaping must be more efficient than swimming.

The energy cost of leaping must be compared with that of continuous swimming very close to the surface. This is because during rapid swimming, as in escape behaviour, the rate of respiration increases, and the animals are therefore constrained to the surface layer. The extra energy required for jumping is

* Permanent address: Department of Aeronautical Engineering, Technion, Haifa, Israel.

approximately (neglecting air resistance)

$$J = WH(1+m) \quad (1)$$

where W is the weight of the dolphin, H is the maximum height of the centre of gravity above the undisturbed sea level, and m is a correction term accounting for the spray carried along with the dolphin as it emerges. The dolphin is approximately neutrally buoyant¹ and so very little energy is required to raise the centre of gravity to surface level. The energy in equation (1) will be compared with that expended by a dolphin swimming continuously with its blowhole just out of the water. This swimming would be roughly equivalent to that of leisurely or cruising swimming, where no more than one-third of the body is out of the water at any instant.

The energy required for swimming at one equivalent body radius beneath the undisturbed surface (that is just submerged) is

$$E = DL \quad (2)$$

where D is the hydrodynamic drag and L is the distance travelled. The drag can be written as²

$$D = \frac{1}{2}\rho_w V^{2/3} C_D \gamma U^2 \quad (3)$$

where ρ_w is the density of water, V is the dolphin volume, C_D the drag coefficient in deep water, γ the correction due to proximity to the surface^{3,4}, and U the swimming speed. Dolphins usually leap only for short periods so that other energy saving aspects of swimming, as when using beat-and-glide or diving⁵, are not applicable.

Fig. 1 A 'running' eastern spinner dolphin (*Stenella longirostris*) leaping approximately two body lengths in the rapid swimming mode. Photograph by R. Pitman.

We now write the ratio of energy J/E to find the range of speeds at which this ratio is < 1 , that is leaping is energy sparing. The energies must be compared over the same distance and therefore the length of the jump as a function of swimming speed has to be known. We neglect air resistance. The leaping dolphin has an approximate ballistic trajectory, for which the distance crossed while the centre of gravity of the animal is out of the water is

$$L = \frac{U^2}{g} \sin 2\alpha \quad (4)$$

where g is the gravitational constant and α the emergence angle, measured from the horizon. The maximum height reached by the centre of mass is

$$H = \frac{U^2 \sin^2 \alpha}{2g} \quad (5)$$

The longest leap for given speed U is obtained when $\alpha = 45^\circ$. In this case, designated by subscript 'max',

$$L_{\max} = \frac{U^2}{g}; H_{\max} = \frac{U^2}{4g} \quad (6)$$

Using these results, we obtain the ratio J/E :

$$R = \frac{J}{E} = \frac{\rho_d g V \frac{U^2}{4g} (1+m)}{\frac{1}{2}\rho_w V^{2/3} C_D \gamma U^2 \frac{U^2}{g}} = \frac{\rho_d g (1+m) V^{1/3}}{2\rho_w C_D \gamma U^2} \quad (7)$$

where ρ_d is the density of the dolphin. Equation (7) shows that for a given dolphin swimming as described, the ratio R decreases monotonically as forward speed U increases. Thus, for every species, there will be a range of speeds for which leaping will be more efficient than shallow swimming. The lowest (crossover) speed at which this occurs is obtained by setting $R = 1$ in equation (7). This speed U_c is dependent on the size of the dolphin (through the volume V), its density, its shape (which will define C_D and m), and how far beneath the surface it swims (which defines γ).

Table 1 Predicted values of crossover speed U_c over which leaping becomes energy sparing as a function of body volume

V (m ³)	U_c (m s ⁻¹)	L_c (m)	H_c (m)	E (J)
0.005	3.34	1.14	0.28	17
0.05	4.90	2.45	0.61	368
0.1	5.50	3.09	0.77	928
0.15	5.89	3.54	0.88	1,590
0.2	6.18	3.90	0.97	2,340
0.25	6.41	4.19	1.05	3,160
1	8.08	6.66	1.67	20,100
5	10.57	11.40	2.85	172,000

Predicted leap length and height are shown, as well as the energy required for each leap ($g = 9.8 \text{ m s}^{-2}$). For any given volume, underwater motion at less than U_c is less energy-consuming than leaping the same distance. A volume of 1 m^3 corresponds to a weight of 1,025 kg.

To obtain specific values of the crossover speed, we substitute typical values of the different parameters in equation (7). The dolphin's density is affected by the degree of lung inflation and the extent of fat reserves. We take it to be approximately equal

to the density of sea water¹, that is, $\frac{\rho_d}{\rho_w} = 1$. The spray mass

coefficient is obtained from the longitudinal added mass, defined as the mass of water carried along when a body moves through a fluid. Thus when the dolphin leaves the water, this mass is carried along. The added mass coefficient for fusiform, elongated shapes such as the dolphin's is $^6 m = 0.2$. Hoerner² gives the relationship between the drag coefficient C_D based on volume and skin frictional drag C_f as

$$C_D/C_f = 4(l/d)^{1/3} + 6(d/l)^{1/2} + 24(d/l)^{2/7}$$

which gives a ratio of 8 for a dolphin with an l/d ratio of about 5, where d = diameter and l = length. Hoerner's Fig. 22 shows C_f to be between 0.002 and 0.003 for semi-turbulent flow in the appropriate range of Reynolds number, so that C_D was approximated here as 0.02. The surface effect correction γ is taken as 4.5 when the body is fully submerged, just below the surface. (If the dolphin were an exact body of revolution $\gamma = 5$)^{3,4}. Both C_D and γ should be considered approximations, C_D because it may be a conservative estimate for a flexing body and γ because it is sensitive to submerged depth and decreases rapidly to 1 at a depth three times the body diameter. Substituting all the above values in equation (7) and setting $R = 1$, we obtain

$$U_c = 65.3 V^{1/3}$$

where U_c is in m s^{-1} and V in m^3 . This general equation, while only an approximation for any specific dolphin, should give a good estimate of the expected speeds above which leaping will occur. Table 1 gives the values of the crossover speed, U_c , as a function of body volume.

Table 1 indicates that for the usual size range (0.05–0.10 m³) of most dolphin species^{7,8}, the crossover speed is about 5 m s⁻¹ (10 knots), well within their available range of speeds⁹. During January and February 1977 and 1979, the RV David Starr Jordan approached various dolphin species (*Stenella* spp., *Delphinus delphis*) at speeds of 4.5–5 m s⁻¹ (9–10 knots) in the eastern tropical Pacific. At that speed, the vessel could approach close to all schools as long as they could be tracked. However, it often took an hour for the ship to close onto schools initially seen at about 2 miles (3.6 km) distance. Evidently those dolphins were mostly moving at cruising speeds of 3.5–4 m s⁻¹ (7–8 knots), similar to previous measurements. We observed that the leaping (running) mode occurred primarily after the ship had closed to within 500 m and the animals had become increasingly alarmed and had noticeably increased speed. No measurements of actual speed were possible as the leaping dolphins usually escaped abeam and when followed, continued along curved paths. The speeds attained appeared somewhat greater than that of the ship and were probably in excess of the crossover speed. The actual crossover speed is probably within 10% of the predicted value. Thus, because of their shallow swimming ($\gamma \approx 4.5$), the crossover speed must be approximately 5 m s⁻¹ (10 knots), and dolphins must leap to obtain higher speeds efficiently.

Swimming speed can be estimated indirectly by measuring the distance between the emergence spot and the re-entry splash on photographs similar to Fig. 1, and comparing it to animal length. These distances were within the range of 2–4 m, as expected from Table 1. The height of the leaps (to the centre of gravity) is between 0.6 and 1.0 m, also in agreement with Table 1. Spotted and spinner dolphins (*S. attenuata* and *S. longirostris*) have been observed leaping distances of about three body lengths (5.4 m) when chased closely by speedboats, corresponding to a swimming speed of ~ 7.3 m s⁻¹ (14.6 knots)¹⁰. After escaping purse seine nets, they continued leaping for 1,500 m, performing leaps of ~ 2.3 body lengths, which corresponds to a speed of 6.4 m s⁻¹, also greater than the crossover speed.

Larger cetaceans ($V > 1$ m³, weight > 1 ton) probably cannot leap during fast swimming, as the energy required for leaping increases rapidly with body size (Table 1). Fishes, on the other hand, do not have to break surface to breathe and can stay sufficiently deep for surface proximity effects to be negligible ($\gamma = 1$). Crossover speed would then be increased by a factor of more than 2, and, except for large fish such as istiophorids and some large scombrids, is not likely to be an important factor in swimming.

Although the cetacean running mode has been described in the context of escape behaviour, it could occur in any situation where rapid speeds for short periods were required. Furthermore, leaping behaviour is not restricted to the running mode. At any speed, individual dolphins will often 'splash leap', that is leap out of the water with various contortions so as to re-enter with a large splash. The various attitudes of such leaps indicate, however, that they are not primarily related to horizontal velocity. Their function is most probably that of display-communication, the exact meaning depending on the situation, including the physiological state of the animal.

We thank Lorraine Prescott and Paul Webb for their help.

Role of the blastocoele microenvironment in early mouse embryo differentiation

Roger A. Pedersen*^{†‡} & Akiko I. Spindle[†]

[†] Laboratory of Radiobiology and [‡] Department of Anatomy, University of California San Francisco, California 94143

During preimplantation development, the mouse embryo differentiates into an outer layer of cells, the trophectoderm, and an inner group, the inner cell mass. Tarkowski and Wróblewska¹ proposed that this differentiation depends on the position of blastomeres in the morula, with outside cells giving rise to trophectoderm and inside cells producing the inner cell mass. This epigenetic hypothesis has been confirmed by other studies in which blastomere position was altered at the 4-cell or 8-cell stage, thus demonstrating the totipotency of the blastomeres at these stages^{2–4}. It was recently found that the inner cell mass of the early blastocyst is also totipotent and can form trophectoderm when isolated by immunosurgery^{5–8}. Because inner cells apparently become committed during the time that they are exposed to the distinct microenvironment of the blastocyst^{9–11}, we postulated that diffusible components or other factors in the blastocoele may have a role in the commitment of cells in the inner cell mass. We report here results, obtained by injecting donor cells into host blastocysts, showing that totipotent cells exposed only to blastocoele fluid differentiate into morphologically normal blastocysts, whereas those in contact with the blastocyst's inner surface do not.

The influence of the blastocoele microenvironment on development of 8-cell and morula-stage embryos was tested by injecting them into the blastocoele of giant chimaeric blastocysts formed by aggregating 8–10 embryos at the 4- to 8-cell stage. These host chimaeras were cultured 48 h, and at the expanded blastocyst stage they were immobilised with a micropositioner and a hole was made in the host trophectoderm with two hand-held glass needles. The zona pellucida of the donor embryo was either kept intact for exposure to diffusible components of blastocoele fluid or removed to allow intimate contact with the inner surface of the host embryo. The donor embryo was inserted into the blastocoele of the host chimaera, which was then allowed to heal. Donor embryos were scored at 24 and 48 h after surgery for escape, arrest, formation of a blastocoele cavity, or formation of a structure without a blastocoele. Some donor embryos were then removed from the host microenvironment by dissection or immunosurgery¹² and tested for their ability to form trophoblast outgrowths *in vitro*.

Host chimaeras readily accommodated the donor embryo within the blastocoele (Fig. 1a), although the host's cavity began to collapse within minutes after an opening was made in the trophectoderm. The procedure required approximately 5 min and was technically difficult to perform on host embryos that were in early stages of expansion. Ten to fifteen host chimaeras were injected in each experiment. In most chimaeras the trophectoderm healed within several hours, as indicated by the reappearance of the host blastocoele cavity.

Two-thirds of the donor embryos that were injected with their zona pellucida intact at the 8-cell or morula stage developed into morphologically normal blastocysts within the host blastocoele (Fig. 1b, c, Table 1). Approximately a fifth of the donors escaped or were unscorable because the host blastocoele failed to reappear, indicating irreparable damage to the host trophectoderm. A few donors arrested at the 8-cell or morula stage, but

* To whom correspondence should be addressed.

their frequency did not exceed that of control (uninjected) donor embryos (data not shown). After 48 h of culture some donor embryos hatched but remained free floating within the host blastocoele. When these embryos were removed from the host and cultured, they formed outgrowths that had 15–20 trophoblast giant cells like those found in trophoblast outgrowths from normal blastocysts^{13,14}.

Table 1 Injection of zona-intact 8-cell and morula-stage embryos into chimaeric blastocysts*

Stage of donor	No. of donors injected	Fate of donor		
		Unscorable	Arrested	Blastocyst
8-cell	31	8	2	21
Morula	26	2	6	18
Total	57	10 (18%)	8 (15%)	39 (68%)

* Methods as in Fig. 1.

In contrast to the intact donors, only a tenth of the donors that were injected without a zona pellucida developed into blastocysts (Table 2). More than half the donors, however, formed compact structures that were in intimate contact with host cells and lacked a blastocoele (Fig. 2a). Approximately a third of the donors escaped or were otherwise unscorable owing to collapse of the host trophectoderm; a few donors were arrested at late cleavage stages. The compact structures were generally attached to the inner surface of the host trophectoderm but occasionally were in contact with the host inner cell mass. To determine whether donor embryos formed compact structures as a result of their trophectoderm cells becoming integrated into the host, we labelled donor embryos with ³H-thymidine before transfer to the host blastocoele. Our preliminary experiments show that intense autoradiographic labelling was restricted to the compact structure (Fig. 2a, Table 3). Fewer grains were seen in host trophectoderm cells that were in direct contact with the donor and occasional grains were found in other host cells. We suggest that donor cells were retained within the compact structure and that the host cell labelling may have been due to transfer and reutilisation of thymidine by host trophectoderm. The thymidine labelling conditions used here (10^{-2} μ Ci ml⁻¹ for 4 h) have been shown not to be toxic to early mouse embryo development¹⁵.

Table 2 Injection of zona-free 8-cell and morula-stage embryos into chimaeric blastocysts*

Stage of donor	No. of donors injected	Fate of donor			
		Unscorable	Arrested	Blastocyst	Compact structure
8-cell	54	23	2	5	24
Morula	80	16	3	10	51
Total	134	39 (29%)	5 (4%)	15 (11%)	75 (56%)

* Methods as in Fig. 2.

To define their developmental potential further we removed the compact structures from host chimaeras 2 days after injection and cultured them in conditions that allow post-implantation development¹⁶. In three experiments, 21 of 27 compact structures derived from zona-free donor morulae formed outgrowths. The outgrowths had 5–15 giant cells, and about half had central clumps of cells resembling inner cell mass derivatives (Fig. 2b). Three compact structures failed to develop, two formed blastocysts, and one formed only an inner cell mass derivative.

We interpret the results of injecting zona-intact donors into chimaeric blastocysts to indicate that diffusible substances that are contained within the blastocoele fluid do not inhibit differentiation of totipotent cells into trophectoderm. Austin and Lovelock¹⁷ showed that the rat or hamster zona pellucida is readily permeable to 1,200-molecular weight dyes. Thus, all small ions, amino acids, vitamins, hormones and other small metabolites present in blastocoele fluid should pass through the zona. The mouse zona appears to be permeable to at least some high molecular weight substances, because antibodies can affect development^{18,19} and immunosurgery can be carried out with

Fig. 1 Chimaeric blastocysts injected with intact donor morulae. *a*, Immediately after injection (phase-contrast, $\times 225$). Donor embryo with intact zona pellucida is in host blastocoele. *b*, After 24-h culture (differential interference contrast, $\times 195$). Donor embryo has developed into morphologically normal blastocyst. *c*, Embryo from *b* fixed and sectioned (bright field, $\times 215$). Embryos were obtained from Dub: (ICR) mice (Flow Laboratories) after superovulation and mating and were cultured in standard egg culture medium as previously described²⁴. Embryos for host chimaeras were obtained on the second day of pregnancy at the 2-cell stage. They were cultured overnight and made into chimaeras by aggregating 8–10 zona-free 4- to 8-cell embryos in phytohaemagglutinin²⁵. Chimaeras were cultured individually in microdrops of medium under a layer of paraffin oil for an additional 3 d. Donor embryos were obtained on the third day of pregnancy at the 8-cell or morula (12- to 16-cell) stage and were inserted into the blastocoele of chimaeras as described in the text. Embryos were fixed and sectioned as previously described¹⁶.

embryos that have an intact zona pellucida¹². As a control, however, we ruptured but did not remove the zonae of eight 8-cell embryos before transfer to host blastocoeles in order to allow free interchange of fluid between the host blastocoele and the donor perivitelline space. Six of the donors developed into blastocysts (one escaped from its zona and formed a compact structure attached to the host trophoblast, and one escaped from the host blastocoele). This result shows that even high molecular weight components of the blastocoele fluid do not alter the differentiation of totipotent donor cells.

The results of injecting zona-free embryos into chimaeric blastocysts cannot be interpreted with certainty because we do not yet know the identity of cells in the compact donor structures. Despite their failure to accumulate blastocoele fluid, the compact structures retained the ability to form trophoblast outgrowths when isolated by immunosurgery. In this respect they resembled inner cells isolated from early blastocysts⁵⁻⁸. Contact with host cells may have altered or delayed the differentiation of donor cells into trophoblast, or it may have physically prevented them from accumulating blastocoele fluid.

Fig. 2 Structures formed by zona-free morulae injected into chimaeric blastocysts. Host chimaeras were made and donor morulae were injected as described in Fig. 1, except that the zona pellucida was removed by a 3–4-min treatment in 0.5% pronase. *a*, Donor morula labelled with ³H-thymidine, injected into host, fixed after 24 h culture, and sectioned (bright field, $\times 240$). Note grains over nuclei of compact structure attached to inner surface of host trophoblast (arrow). For labelling of donor cells, morulae were incubated for 4 h in $10^{-2} \mu\text{Ci ml}^{-1}$ ³H-thymidine (specific activity, 40 Ci mmol^{-1}), washed extensively, and incubated in unlabelled medium at least 2 h before transfer to the host blastocoele. For autoradiography, embryos were fixed and sectioned as described previously¹⁶, except that the uranyl acetate treatment was omitted. They were exposed to Kodak NTB emulsion for 2 months. *b*, Outgrowth formed by compact structure (phase-contrast, $\times 128$). After injected chimaeras were cultured 48 h in standard medium, compact structures were removed by immunosurgery and cultured in microdrops of modified Eagle's medium on tissue culture dishes (Falcon) for 6 d by the methods previously described¹².

Table 3 Fate of ³H-thymidine label in donor nuclei*

Location of nuclei	No. of nuclear sections scored	Labelled nuclei (%)	Grains per labelled nucleus (mean \pm s.e.m.)
Compact structure	140	94.3	44.5 \pm 31.5
Trophoblast:			
In contact with compact structure	19	89.5	14.3 \pm 11.4
Not in contact with compact structure	286	25.2	2.0 \pm 1.1

* The embryo shown in Fig. 2*a* was fixed and serially sectioned for autoradiography. Grains were counted over nuclei in 15 sections.

Because morphological features are not adequate for distinguishing between these possibilities, we are currently assessing the biochemical status of the compact structures using two-dimensional protein patterns²⁰ to identify inner cell mass and trophoblast. In any case, it seems that intimate contact between totipotent donor embryos and the blastocoele surface of host embryos alters the donors' morphological development. An understanding of the mechanism for this effect may provide clues to the nature of the interaction between inner and outer cells of intact blastocysts. The physical bases of such interactions could include gap junctions²¹, other elements of the cell surface²², or the extracellular matrix²³.

Although we have not excluded the possibility that components of blastocoele fluid can act in concert with non-diffusible components to affect the differentiation of totipotent cells placed in the blastocoele, our results show clearly that blastocoele fluid alone does not alter the early morphological development of totipotent donor embryos. This conclusion is consistent with the fact that trophoblast cells are continuously exposed on their interior surfaces to the fluid that they produce in normal blastocysts. Our results further indicate that the mouse trophoblast can accumulate fluid even when exposed to the higher concentration of ions present in blastocoele fluid, which is consistent with active ion transport¹¹.

We thank Ms Kitty Wu for histology, Mr David Akers for photography, Drs John Levinson and Terry Magnuson for their comments, and Ms Naomi Sinai and Ms Mary McKenney for their assistance with the manuscript. This work was supported by the US Department of Energy.

‡ Laboratory of Clinical Investigation, National Institutes of Health, Bethesda, Maryland

Immunodeficiency disorders have provided much information on the development and interaction of the various B and T lymphoid components in the immune system of man. As the lymphoid system becomes increasingly divided into functional subsets of cells it will be important to find immunodeficiencies affecting newly discovered cell types. Natural killer (NK) cells are a recently described but ill-defined subpopulation of lymphocytes which is thought to play an important part in surveillance against tumour development¹. Mice homozygous for the *beige* gene were found to have a selective deficiency in NK function² and were more susceptible to transplantation of syngeneic tumours as predicted^{3,26}. We report here that patients carrying the analogous, autosomal recessive Chediak-Higashi (CH) gene have a profound defect in their ability to spontaneously lyse various tumour cells *in vitro* by either antibody-dependent or independent mechanisms. Since other cell-mediated cytolytic functions were relatively normal, these results suggest that the *beige* or Chediak-Higashi gene in both man and mouse controls NK function.

§ To whom correspondence should be addressed.

The Chediak-Higashi syndrome in man is a rare, genetically determined disease manifested clinically by abnormal leukocyte granulation, defective pigmentation and an increased susceptibility to infections⁴. Humoral immunity and delayed type hypersensitivity are normal⁵ and children usually die of pyogenic infection, presumably resulting from a host defence abnormality related to defective granules in their polymorphonuclear (PMN) leukocytes^{4,6}. Survivors generally succumb to a lymphoproliferative disorder which may be malignant⁷.

In the present study, two male patients, Lewis R. (age 29 yr) and Larry R. (age 28), siblings from a consanguineous marriage, and eight different age and sex matched normal controls were studied in parallel experiments on three separate occasions over a 1-month period. The detailed clinical history and many previous experiments on these patients have been described elsewhere⁸⁻¹⁰. In the two CH patients the immune status was normal with respect to (1) serum immunoglobulin and complement levels, (2) *in vivo* antibody response to immunisation with *Salmonella typhosa* endotoxin and common vaccines, (3) delayed type hypersensitivity to mumps, *Candida*, dinitrochlorobenzene and SKSD (streptokinase-streptodornase-varidase), and (4) *in vitro* proliferative responses to various lectins such as concanavalin A, phytohaemagglutinin and pokeweed mitogen. Phagocytic function was also normal. At the time of study the patients were free of overt infection, and were not undergoing treatment.

To investigate NK function, peripheral blood was separated by standard Ficoll-Hypaque gradient centrifugation and the mononuclear cell band was selectively depleted of most (>90%) monocytes by adherence to microexudates of detached kidney cell monolayers. As shown in a representative experiment (Fig. 1a) lymphocytes from both CH patients were profoundly depressed in their ability to lyse K562 target cells, a human cell line of myeloid leukaemia origin which is the most sensitive NK target described in the human¹¹. Data pooled from three repeat experiments revealed 85 ± 12 lytic units (LU) per 10^6 cells ($n=6$) for age and sex matched normals and <0.1 LU/ 10^6 ($n=2$) for the CH patients when LU were calculated at 20% lysis. The low response in the CH patients was not altered by

Table 1 The range of cytolytic effector functions of peripheral blood cells from donors with Chediak-Higashi syndrome compared with normals

Effector function	Target cell	Normal controls*		CH donors*	
		Max. lysis†	LU/ 10^6 ‡	Max. lysis	LU/ 10^6
(1) NK (lymphocyte)	Alab	40 (100/1)	40 ± 4	3 (100/1)	<0.01
(2) ADCC (lymphocyte)	Daudi	62 (50/1)	164 ± 30	10 (50/1)	7 ± 2
(3) ADCC (monocyte)	HRBC	43 (100/1)	12 ± 2	43 (100/1)	18 ± 5
(4) ADCC (PMN)	HRBC	60 (100/1)	22 ± 6	59 (100/1)	26 ± 4
(5) Spontaneous (monocyte)	TU5	13 (10/1)	ND	12 (10/1)	ND
(6) Spontaneous (PMN)	K562	34 (20/1)	4 ± 1	30 (20/1)	5 ± 1
(7) Lectin induced (lymphocytes)	P815	73 (5/1)	1,000 ± 80	52 (5/1)	550 ± 320
(8) Lectin induced (PMN)	RBL-5	44 (5/1)	100 ± 6	50 (5/1)	80 ± 25
(9) NK after MLC	K562	33 (40/1)	95 ± 35	1 (40/1)	<0.1

Lines 1, 2: Peripheral blood was separated by centrifugation (1,000g) over Ficoll-Hypaque and the mononuclear cell band was depleted of monocytes by adherence (45 min, 37 °C) to fibronectin microexudates of detached TUS kidney cells grown to confluence²². Cell loss was approximately 20% in all donors and contamination of the recovered lymphocytes was <1% monocytes as judged by phagocytosis of latex beads or nonspecific esterase staining and <2% polymorphonuclear leukocytes (PMN) was indicated by Wright's stained cytocentrifuge preparations or staining with a specific monoclonal, anti-human PMN antibody (provided by Dr P. Beverley, University College Hospital, London). Lymphocytes were tested in a 4 h ^{51}Cr release assay against an NK-sensitive target, Alab (breast carcinoma), or an NK-insensitive target, Daudi (IgM bearing EBV lymphoma), pretreated with a 1/50 dilution of rabbit anti-human IgM. Non-antibody treated Daudi cells were lysed 15% by normals and 1% by CH patients at a 50/1 E/T ratio. **Lines 3, 4:** Mononuclear cells (74% lymphocytes, 23% monocytes) obtained by Ficoll-Hypaque separation consisted of approximately 72% E rosette forming cells (T cells), 10% slg^+ cells (B cells) and 27% FcR^+ cells (IgG) with no significant differences between donors. PMN were obtained by dextran sedimentation of Ficoll-Hypaque pellets and consisted of approximately 80% FcR^+ cells, 90% of which phagocytosed bovine erythrocytes coated with rabbit anti-bovine erythrocyte antibody (IgG). Effector cells were tested in an 18-h ^{51}Cr release assay against human erythrocytes (A^+) pre-coated with a 1/10 dilution of rabbit IgG anti-HRBC antibody. **Line 5:** Ficoll-Hypaque purified mononuclear cells were incubated on microexudates and adherent cells (4-7%) were recovered by EDTA treatment and vigorous shaking. Effectors (>90% latex⁺, and nonspecific esterase⁺) were tested in a 48 h, ^3H -thymidine release assay against TU5 target cells (SV40 transformed mouse kidney cells). **Line 6:** Cell pellets from Ficoll-Hypaque were sedimented on dextran followed by re-centrifugation on a Ficoll-Hypaque-Percoll mixture²³. Purified populations were 99% PMN as indicated by morphology and staining with monoclonal anti-PMN antibody. Effectors were tested in a 36 h cytostasis assay as measured by inhibition of ^3H -TdR uptake during a 12-h pulse. Cytostasis against K562 was not inhibited by catalase²³. **Lines 7, 8:** Lymphocytes or PMN prepared as described above were tested in an 18-h ^{51}Cr release assay against P815 (mouse mastocytoma) or RBL-5 (Rauscher leukaemia virus induced murine lymphoma) targets in the presence of 2 or 20 $\mu\text{g}/\text{ml}^{-1}$ phytohaemagglutinin (PHA) respectively. No lysis occurred in the absence of PHA and these concentrations were not toxic. The predetermined optimum PHA concentrations were identical in careful titration experiments, between normals and CH patients. **Line 9:** Mononuclear cells were cultured 7 d together with a pool of irradiated stimulator cells pooled from four normal allogeneic donors as described previously²⁴. Effectors were collected and tested in a 4-h ^{51}Cr release assay against K562 cells, an HLA negative target. Lysis by non-stimulated cultures was approximately half the values shown.

* Two CH patients (Le.R., La.R.) and 2-6 normal, age and sex matched controls were studied in parallel experiments.

† Mean % lysis in triplicate wells at the effector/target ratio given in brackets. These values occurred on the plateau of effector titration curves.

‡ A lytic unit was defined as the number of effector cells required for 20% lysis. ND, not determined.

Fig. 1 Impairment of NK and ADCC activity in lymphocytes from Chediak-Higashi (CH) patients. Ficoll-Hypaque separated, peripheral blood lymphocytes were depleted of monocytes on microexudates and incubated with ^{51}Cr -labelled K562 cells, a human myeloid leukemia cell line (a), or antibody-coated Chang cells, a human hepatocarcinoma cell line (b) at various effector-to-target ratios in a 4-h cytolytic ^{51}Cr release assay. ●, J.R.; ▲, J.O. (normal donors); □, La.R.; ○, Le.R. (CH patients). Values represent the mean % specific lysis \pm s.e. in triplicate wells. Lysis of non-antibody coated Chang cells at a 50/1 effector/target ratio was 18, 7, 2, and 1.5% for J.R., J.O., La.R. and Le.R., respectively.

prolonged incubation time (up to 24 h) and was evident in tests of six different NK-sensitive target cell lines including MOLT-4, Alab, CEM, MDA and human fetal fibroblasts (data not shown). The NK defect persisted during a 7-d incubation *in vitro* with or without stimulator cells (Table 1, line 9). As shown in Fig. 1b, lysis of Chang cells, precoated with an optimum dose of rabbit anti-Chang antibody, was also severely depressed. The degree of cytolytic depression was similar against antibody-coated Daudi targets, a human lymphoblastoid cell line (Table 1, line 2) and lysis of antibody-coated RBL-5, a murine tumour, was also markedly impaired although less so than the response against human tumours (unpublished observation). The failure of CH lymphocytes to efficiently lyse human tumours cells was not due to a generalised block in the antibody-dependent cell-mediated cytotoxicity (ADCC) mechanism. Hence mononuclear effector cells and polymorphonuclear leukocytes (PMN) from CH patients lysed antibody-coated human erythrocytes in a normal fashion as shown in Table 1 (lines 3, 4). When combined with the cell fractionation studies shown in Table 2, these results suggest

Table 2 Fractionation of NK and ADCC effectors

Expt	Fractionation	% Lysis of K562*		% ADCC*	
		Normal	CH	Normal	CH
1	FcR ⁺	29	4	36	3
	FcR ⁻	6	0.2	1	0
2	Unseparated	51(14)	5(<1)	59(97)	10(<1)
	G-10 passed	53(53)	1(<1)	64(133)	22(4)
3	Unseparated	22(9)	2(<1)		
	Nylon passed	39(11)	0.4(<1)		
4	Microexudate	60(50)	7(0.3)		
	Microexudate + interferon	75(100)	14(4.0)		

Expt 1: Peripheral blood mononuclear cells were depleted of monocytes by a 1-h incubation on plastic surfaces. Lymphocytes were then incubated 60 min at room temperature in plastic flasks (Falcon) pre-coated with trinitrophenylated (TNP) fetal calf serum (FCS) and rabbit anti-TNP antibody²⁵. Non-adherent lymphocytes (FcR⁻) were recovered in the supernatant and adherent cells (FcR⁺) were eluted with EDTA and scraping. FcR⁺ and FcR⁻ fractions were incubated overnight at 37 °C to allow recovery before assay. **Expt 2:** Mononuclear cells were passed through a 10-ml column of Sephadex G-10 equilibrated with medium containing 20% FCS. Cell recovery was 60% of input. **Expt 3:** Mononuclear cells were passed through a 10-ml column packed with scrubbed nylon wool (Fenwall). Cell recovery was 50% of input. **Expt 4:** Mononuclear cells were depleted of monocytes on microexudates and preincubated for 1 h with 10^3 units ml^{-1} human fibroblast interferon (HEM Research) or medium as control, washed and assayed for cytotoxicity.

* Effectors were assayed in a 4-h ^{51}Cr release assay against K562 cells or RBL-5 cells pretreated with rabbit anti-mouse thymocyte serum. Values represent the mean % lysis in triplicate wells at a 50/1 E/T ratio and the numbers in brackets represent lytic units per 10^6 calculated at 20% lysis.

that the defect in ADCC and NK in CH patients is confined to a subpopulation of FcR⁺, non-adherent lymphocytes selectively blocked in their ability to lyse tumour cell targets.

The selectivity of the antibody-independent NK cell defect is shown in Table 1. Lymphocytes were blocked in their ability to spontaneously lyse tumour cell targets whereas cytolysis of tumour cells by monocytes was normal (line 5). Surprisingly, cytotoxicity by PMN from CH patients against K562 cells was also normal (line 6), as was lectin-generated killing by this cell type (line 8). Since lysosomal enzymes and degranulation are abnormal in CH patients (reviewed in refs 4, 6) these results suggest that lysosomal granules are not involved in PMN cytotoxicity or cytolysis against these target cell lines. The population of T killer cells, as measured by lectin-dependent cytolysis was normal in one patient (Le) but low in the other (La, line 7). A more extensive study is required before a definitive statement on the status of cytolytic T cells can be made. However, T-cell mediated immunity in general was previously shown to be normal in these and other patients as judged by skin testing and proliferative responses to T-dependent mitogens⁸⁻¹⁰.

Table 3 Frequency of target binding cells

Donor	Fractionation	% TBC		
		K562	Molt-4	P815
Normal	Nylon wool passed	24 \pm 4*	37 \pm 3	2 \pm 1
CH	Nylon wool passed	25 \pm 2	36 \pm 4	3 \pm 2
Normal	G-10 passed	15 \pm 2	37 \pm 3	ND
CH	G-10 passed	15 \pm 1	43 \pm 5	ND

Ficoll-Hypaque separated peripheral blood lymphocytes were passed over nylon wool or Sephadex G-10 columns to remove adherent cells and mixed with a fivefold excess of tumour cells. Cell mixtures were centrifuged (150g) 5 min, incubated for 5 min at 37 °C and then stored on ice. Pellets were gently resuspended and the number of lymphocytes binding to tumour cells (TBC) was determined in triplicate samples by size discrimination in a haemocytometer as described previously¹³.

* Values represent the mean \pm variance of %TBC values for two individuals. Nylon wool passed or G-10 passed cells from normals yielded 55%, 46% and 1% lysis of K562, Molt-4 and P815 respectively in a 4-h ^{51}Cr release assay, at a 100/1 E/T ratio. Lysis by CH cells was below 5%. ND, not determined.

Further experiments suggested that the CH defect may lie within the lytic pathway rather than at the level of population size. As shown in Table 3, non-adherent lymphocytes from CH patients were completely normal in their ability to bind and lyse K562 and Molt-4 targets, whereas P815, an NK-insensitive target, was not bound or lysed by CH or normal donors. Most of the lymphocytes binding to tumour cells (TBC) detected in this system have been shown to represent NK cells in the mouse¹² and in the human TBC can be specifically inhibited by pre-incubation of effector cells with solubilised glycoproteins from NK-sensitive targets¹³. Therefore, if the relative number of TBC in a heterogeneous human lymphocyte population is a reliable estimate of the frequency of NK cells, as in the mouse, then these results suggest that NK cells are present in CH patients but do not function.

Suppressor cells in the NK system appear primarily to be adherent, macrophage-like cells (reviewed in ref. 14). Suppressor cells did not appear to be responsible for the low NK response of CH patients as removal of FcR⁻ cells or cells adherent to Sephadex G-10, nylon, wool or microexudates did not restore the low NK response in CH patients (Table 2). In addition no suppression of cytotoxicity was seen in mixtures of CH and normal lymphocytes, even at the highest ratios tested (2/1, data not shown).

The precise location of the defective gene product in the cytolytic pathway is not known but may involve an impairment of cyclic GMP-mediated triggering of NK cells as: (1) cyclic GMP causes a small but significant enhancement of NK activity in mice whereas cyclic AMP decreases the level of cytotoxicity¹⁵; (2) cyclic GMP or inducers thereof have been shown to improve various defects in CH patients such as abnormal granule

morphology¹⁶, chemotaxis¹⁷ and NK function (P. Katz, unpublished observation), and (3) interferon, which boosts NK activity in CH patients (Table 2) is known to cause a transient increase in cyclic GMP levels in lymphoid cells¹⁸.

Thus we have described the first immunodeficiency disorder in humans with an apparently selective deficit in effector functions mediated by NK cells and cells involved in ADCC. Other studies of the more familiar immunodeficiencies, involving impairments of both B and T cells, failed to reveal significant defects in NK function¹⁹ except in the case of severe combined immunodeficiency²⁰. Impairments of ADCC are more widespread (reviewed in ref. 19) and in one study of X-linked agammaglobulinaemia, ADCC was defective whereas NK activity was normal²⁰. In view of the complexity involved it is not surprising that different genes should control unique steps in an otherwise common cytolytic pathway in a single cell, possibly mediating both ADCC and NK activity as previously suggested (reviewed in ref. 21).

It is intriguing to note that 85% of the 53 CH cases on record entered an accelerated 'lymphoma-like' phase¹⁰. Closer scrutiny of this phenomenon may provide the first direct evidence that NK cells in the human are involved in surveillance against spontaneous tumour development.

Glucocorticoid-induced thymocyte apoptosis is associated with endogenous endonuclease activation

A. H. Wyllie

Department of Pathology, University Medical School Buildings, Teviot Place, Edinburgh EH8 9AG, UK

In near-physiological concentrations, glucocorticoid hormones cause the death of several types of normal and neoplastic lymphoid cell, but the mechanisms involved are unknown^{1,2}. One of the earliest structural changes in the dying cell is widespread chromatin condensation, of the type characteristic of apoptosis, the mode of death frequently observed where cell deletion seems to be 'programmed'^{3,4}. It is shown here that this morphological change is closely associated with excision of nucleosome chains from nuclear chromatin, apparently through activation of an intracellular, but non-lysosomal, endonuclease.

Fig. 1 In methylprednisolone-treated thymocytes the proportion of chromatin cleaved endogenously to small fragments is closely similar to the proportion of nuclei whose morphology shows the generalised chromatin condensation of apoptosis. The graph shows the percentage of total chromatin unsedimented by centrifugation at 27,000g for 20 min in lysates prepared from thymocytes incubated *in vitro* for the times shown, in the presence (●) or absence (Δ) of 10^{-5} M methylprednisolone succinate. Plotted on the same axis is the proportion of nuclei in matched cultures showing the morphology of apoptosis after incubation with (○) or without (△) 10^{-5} M methylprednisolone. Steroid concentrations down to 10^{-7} M gave similar results. All points are means of at least five experiments ± 1 s.e. Cells for chromatin studies were washed free of steroid and growth medium by gentle centrifugation (150g for 10 min) and resuspended in 150 mmol l⁻¹ NaCl, pH 7.0. Aliquots of 600 μ l containing 10^8 cells each were lysed in 10 vol of 25 mmol l⁻¹ acetate buffer, pH 6.6. The lysates were centrifuged at 27,000g for 20 min and acid-precipitable DNA was measured by the diphenylamine reaction¹⁶ in the supernatant, the pellet and aliquots of the original uncentrifuged lysate. Recovery from the 27,000g pellet plus supernatant was consistent at over 82% of the original lysate, and incubation of the lysate at pH 6.6 for up to 20 min at 37°C did not materially alter the proportion of DNA appearing in the 27,000g supernatant. This proportion is expressed as percentage of the total in the uncentrifuged lysate. Cells for morphological study were centrifuged at 150g for 10 min, resuspended in a drop of serum, smeared on glass slides, air dried, fixed in Bouin's fluid and stained by the Feulgen reaction. In each experiment 500 cells were scored for the presence of condensed or normal chromatin.

Suspensions of thymocytes from suckling rats were treated *in vitro* with methylprednisolone succinate for various periods. Thereafter, they were studied by light microscopy to determine the proportion of nuclei with condensed chromatin; matched samples were lysed for measurement of the proportion of chromatin DNA which did not pellet after centrifugation at 27,000g for 20 min. In untreated fresh thymocytes this proportion was near zero, but in treated thymocytes the unsedimented low molecular weight DNA represented an increasing proportion of the total, rising above control levels after 1 h of treatment (Fig. 1). This proportion showed a striking quantitative identity to the proportion of nuclei found to contain condensed chromatin morphologically. The proportion of condensed chromatin also rose progressively with time of exposure to steroid in the treated thymocytes but remained low in the controls (Fig. 1).

Agarose gel electrophoresis showed this low molecular weight DNA to consist of fragments whose molecular weights were integer multiples of a subunit; the length of this subunit—about 180 base pairs—was identical to that of nucleosomes isolated from whole fresh thymocyte nuclei after micrococcal nuclease digestion (Fig. 2). One result of steroid action seemed to be excision from nuclear chromatin of nucleosome chains up to more than 8 units in length. This nucleosome excision was not merely the result of the process of lysis itself, but seemed to have

Fig. 2 The low molecular weight chromatin recovered from steroid-treated thymocytes consists of nucleosome chains with a normal repeat length. *a*, Shows a 1.8% agarose gel stained with ethidium bromide and viewed in UV light. The tracks were loaded with DNA from the 27,000g supernatants of lysates of equal numbers of thymocytes after incubation for 3 or 5 h, as indicated, in the presence of 10^{-5} M methylprednisolone succinate, or, for comparison, with a micrococcal nuclease digest of fresh thymocyte nuclei (MN). Thymocyte DNA was concentrated by precipitation in 70% ethanol and 0.13 mol l^{-1} NaCl, dried under vacuum, redissolved in Tris 10 mmol l^{-1} , EDTA 1 mmol l^{-1} and 1% SDS, pH 7.4, and extracted four times through chloroform:isoamyl alcohol (24:1). *b*, Shows the size of the DNA fragments obtained from thymocytes treated for 5 h with methylprednisolone 10^{-5} M (●) and from fresh thymocyte nuclei digested with micrococcal nuclease (△). Mobilities in 1.8% agarose were calibrated against a *Taq* digest of Φ X174.

occurred within intact cells, as untreated cells showed little or no such excision, whereas treated cells showed excision after lysis by several different non-shearing methods, including the use of cation chelators and SDS.

These results show that glucocorticoid induces in thymocytes an endonuclease-like activity whereby well organised chromatin is subjected to multiple double-strand cleavage events, restricted to the inter-nucleosomal DNA. Moreover, the close quantitative identity between the appearance of morphologically condensed chromatin and the products of chromatin digestion implies that this activity may be present only in cells showing the characteristic generalised chromatin condensation of apoptosis. We do not know whether the chromatin excision is itself responsible for the condensation.

The closely delineated size distribution of the excised DNA fragments suggests that the endogenous digestion involves nuclease activity without concurrent protease activity. This is evidence against the view that the endogenous, steroid-associated digestion is merely the result of lysosomal activation. Histochemistry of apoptotic cells also suggests that lysosomal disruption does not occur^{4,5}.

In conclusion, the results demonstrate the presence within glucocorticoid-treated thymocytes of new endonuclease activity which excises well organised nucleosome chains from chromatin. This activity becomes evident after about 1 h of glucocorticoid treatment and correlates quantitatively with the morphologically observed chromatin condensation of apoptosis. Lysosomal enzymes are apparently not involved.

As inter-nucleosomal chromatin breaks can be produced by non-enzymatic means⁶, the evidence that this steroid-associated activity is enzymatic is at present presumptive. However, nucleases capable of mediating this type of chromatin excision are known to be present in the nuclei of thymocytes⁷ and other cells^{8,9}, and inhibitors of macromolecular synthesis prevent chromatin condensation in steroid-treated thymocytes⁴. One

hypothesis, which we are now testing, is that divalent cations mediate the lethal glucocorticoid effects. It is well established in other systems that divalent cations promote chromatin condensation¹⁰, and are required for nuclease activation^{8,9}. Further, certain manifestations of lethal glucocorticoid action on thymocytes have been shown to be cation dependent^{11,12}, although these manifestations were observed many hours later than the chromatin condensation and nuclease activation recorded here. Internucleosomal chromatin breakage has been recorded in lymphocytes and fibroblasts during death induced by immunological attack (although apparently not during lysis as a result of viral infection)¹³, and also in the terminal differentiation of normoblasts¹⁴ and lens cells¹⁵. This raises the question of whether a class of endonuclease exists whose activation is associated with the programmed destruction of the genome.

Insulin-like stimulation of glucose oxidation in rat adipocytes by vanadyl (IV) ions

Yoram Shechter

Department of Hormone Research, Weizmann Institute of Science, Rehovot, Israel

Steven J. D. Karlish

Department of Biochemistry, Weizmann Institute of Science, Rehovot, Israel

The mechanism of insulin action is still unknown¹. One approach to this problem is to apply substances which mimic the action of the hormone to target cells. Ouabain and deprivation of extracellular K^+ (refs 2, 3), which inhibit the active transport of Na^+ and K^+ ions, are both known to activate glucose transport and oxidation in isolated adipocytes. Vanadate (V) ions have recently been shown to act as very efficient inhibitors of the sodium pump or $(\text{Na}^+ + \text{K}^+)\text{ATPase}$ in *in vitro* preparations⁴. They have a natriuretic and diuretic effect in rats⁵ and a positive inotropic effect on cat heart muscle⁶. Many tissues contain vanadium at a concentration of about 0.1–1.0 μM (ref. 7) and so endogenous vanadate could be a physiological regulator of the sodium pump. But this is still open to debate, because the bulk of the vanadium is probably in the vanadyl (IV) form^{8,9} and VO^{2+} ions bind tightly to proteins^{8,10}. VO^{2+} is a relatively ineffective inhibitor of $(\text{Na}^+ + \text{K}^+)\text{ATPase}$ *in vitro*^{8,11}. We report here that externally applied vanadate ions at low concentrations mimic fully the effect of insulin on glucose oxidation in rat adipocytes. However, this simulation seems to be due mainly to the effects of vanadyl (IV) ions, probably produced within the cells, and not primarily to inhibition of the sodium pump. Also, externally applied vanadyl (IV) ions stimulate glucose oxidation substan-

tially. Vanadyl ions are known to be powerful inhibitors of alkaline phosphatase¹² and we therefore consider the possibility that they inhibit a cellular phosphatase activity. An early event in insulin action may involve alteration of the degree of phosphorylation of protein(s) involved in regulation of sugar transport.

The basic effects of insulin and vanadate on glucose oxidation in adipocytes are summarised in Table 1. There is evidence that in adipocytes the rate of oxidation is limited by the entry of glucose into the cell^{13,14}. Insulin alone routinely stimulated the rate of glucose oxidation by three- to fourfold, and an optimal concentration of vanadate ions in the medium (see Table 1 and Fig. 2) normally produced a 70–100% maximal activation of glucose oxidation. As reported previously¹⁶ externally applied ATP partially inhibited the effect of insulin, and this is also the case with vanadate (Table 1). Also, a non-hydrolysable analogue adenosine 5'-(β , γ -imido)triphosphate (AMP-PNP) was ineffective, as found before with insulin¹⁶. Further evidence for the similarity of the effects of vanadate and insulin is the identical stimulation of glucose oxidation over a wide range of glucose concentrations. The degree of stimulation falls as the glucose concentration in the medium is raised, suggesting that the site of activation is the saturable glucose transport system. Removal of Ca^{2+} from the medium did not affect stimulation of the glucose oxidation by either insulin or vanadate (data not shown).

Table 1 Stimulation of glucose oxidation in fat cells by insulin and vanadate. Effects of ATP and AMP-PNP

Addition	¹⁴ CO ₂ production* (c.p.m. per 2 h \pm s.e.m.)	% Maximal stimulation
None	5,800 \pm 200	0
Insulin (10 ng ml ⁻¹)	24,500 \pm 400	100
Insulin (10 ng ml ⁻¹) + ATP (0.4 mM)	15,000 \pm 100	48
Vanadate† (0.1 mM)	23,000 \pm 220	90
Vanadate (0.1 mM) + ATP (0.2 mM)	18,700 \pm 240	68
Vanadate (0.1 mM) + ATP (1.6 mM)	13,600 \pm 200	41
Vanadate (0.1 mM) + AMP- PNP (0.1 mM)	23,200 \pm 140	92

Isolated fat cells were prepared from Sprague-Dawley rats (80–120 g) according to Rodbell¹⁵. Glucose oxidation was measured by conversion of D-[U-¹⁴C]glucose to ¹⁴CO₂ (ref. 15). The final reaction volume of 0.5 ml contained 0.16 mM glucose and about 3×10^5 fat cells, suspended in Krebs-Ringer buffer (pH 7.4) consisting of: NaCl, 110 mM; NaHCO₃, 25 mM; KCl, 5 mM; KH₂PO₄, 1.2 mM; CaCl₂, 1.3 mM; MgSO₄, 1.3 mM and bovine serum albumin, 7 mg ml⁻¹.

* The absolute rate of glucose oxidation with insulin was 4.8 nmol per 2 h. The assay was run in duplicates.

† Sodium orthovanadate (Na₃VO₄) was applied.

Inhibition of (Na⁺ + K⁺)ATPase and active Na and K transport in red cells¹⁷ and squid axons¹⁸ by vanadate ions has been shown to require the presence of K⁺ in the medium. This was clearly not the case for stimulation of glucose oxidation by externally applied vanadate (see Table 2). Removal of K⁺ from the medium inhibits sodium pump activity and gave a partial stimulation of glucose oxidation as described previously². But addition of vanadate in the K⁺-free medium gave a further near maximal stimulation. In fact the vanadate was somewhat more effective in the K⁺-free than in the normal K⁺-containing medium (compare lines 3 and 6 of each experiment, Table 2).

The data in Fig. 2 provide evidence that the principal form of vanadium involved in stimulation of glucose oxidation is the vanadyl ion. The K_{0.5} for externally applied ortho vanadate was about 20 μ M. Addition to the medium of the reducing agent glutathione (GSH) (see refs 4, 11) lowered the concentration of added vanadate for a half maximal stimulation by almost one order of magnitude (K_{0.5} = 3 μ M). GSH (1.2 mM) itself

Fig. 1 Rates of glucose oxidation with insulin and vanadate at increasing concentrations of glucose. Isolated fat cells (about 3×10^5 cells) were incubated for 2 h at 37°C in the conditions described in Table 1, except that the D-[U-¹⁴C]glucose was diluted with unlabelled D-glucose to give the final concentrations indicated. Samples containing either insulin (10 ng ml⁻¹, ●), Na₃VO₄ (0.2 mM, △) or no addition (○) were run in duplicate.

produced a small but significant stimulation of the rate of glucose oxidation in these cells (5–15% of the rate of saturating insulin concentrations)¹. Adrenaline (200 μ M) also increased the effectiveness of suboptimal concentrations of vanadate (not shown). Addition of vanadyl ions directly to the incubation medium produced a substantial but incomplete stimulation of glucose oxidation, with an apparent K_{0.5} of ~25 μ M. The presence of GSH did not affect maximal stimulation or the apparent affinity for this effect of VO²⁺. Control experiments showed that solutions of vanadyl sulphate above 100 μ M at neutral pH become cloudy, and so the lack of full stimulation is probably attributable to limited solubility of VOSO₄.

In red cells externally applied vanadate is transported into the cell on the anion carrier¹⁰, and is reduced largely to the vanadyl ion (IV) which itself is bound tightly to haemoglobin⁸. In adipocytes also, preliminary measurements using the vanadyl (IV) ESR signal, indicate that externally added vanadate or vanadyl ions penetrate into the cells and vanadate (V) is reduced to the vanadyl (IV) state by the endogenous reducing compounds (H. Degani, Y.S. and S.K., unpublished data). Both internally generated vanadyl ions and externally applied vanadyl ions become bound to intracellular components (H. Degani, Y.S. and S.K., unpublished). Glutathione is known to be lost from many cells when they are incubated in a GSH-free medium¹⁹. Thus externally applied GSH (see Fig. 2) may enter the adipocytes and supplement the endogenous reducing power, shifting the ratio of vanadate to vanadyl in the direction of vanadyl. The higher concentrations of VO²⁺ required, compared to vanadate plus GSH could reflect slow penetration or binding of VO²⁺ to

Table 2 Stimulation by vanadate ions of glucose oxidation in a K⁺-free medium

Expt	Condition	¹⁴ CO ₂ production (c.p.m. \pm s.e.m.)
26979	K ⁺ -containing medium	7,775 \pm 426
	+ insulin (4 ng ml ⁻¹)	23,200 \pm 201
	+ Vanadate (100 μ M)	14,850 \pm 652
	K ⁺ free medium	17,000 \pm 1500
241079	+ Insulin (4 ng ml ⁻¹)	23,850 \pm 50
	+ Vanadate (100 μ M)	22,875 \pm 727
	K ⁺ containing medium	5,650 \pm 351
	+ Insulin (10 ng ml ⁻¹)	20,100 \pm 500
	+ Vanadate (100 μ M)	14,425 \pm 20
	K ⁺ -free medium	7,700 \pm 201
	+ Insulin (10 ng ml ⁻¹)	19,650 \pm 952
	+ Vanadate (100 μ M)	16,400 \pm 301

Glucose oxidation was carried out as described in the legend to Table 1. In the K⁺-free medium KCl was omitted and NaH₂PO₄ replaced KH₂PO₄.

Fig. 2 Rates of glucose oxidation at 0.14 mM glucose were measured as in Table 1. In this experiment maximal stimulation by insulin was 445% of the control value. Where indicated reduced glutathione was present at a concentration of 1.2 mM. The small stimulation of glucose oxidation by GSH alone was subtracted from that observed in the presence of vanadate or vanadyl ions.

the albumen in the medium. Specific ^{125}I -insulin binding to the adipocytes was not affected by vanadate (not shown).

In the light of these results it is unlikely that added vanadate acts primarily by inhibiting $(\text{Na}^+ + \text{K}^+)\text{ATPase}$. The vanadate ion is known to affect several enzymes involved with phosphate or phosphate substrate metabolism²⁰. However, the effective species in our experiments seems to be the vanadyl ion which is known to inhibit strongly alkaline phosphatase¹². If in the adipocytes the vanadyl ions inhibited a phosphatase activity this could imply a connection between the degree of phosphorylation of cellular proteins (the glucose carrier itself?) and regulation of glucose entry by insulin or vanadate. Insulin has been shown to stimulate phosphorylation of certain proteins in adipocytes equilibrated with orthophosphate^{21,22}. The steady state level of phosphorylation should reflect the balance between the relevant phosphorylating and phosphatase activities. Insulin action could be accompanied by inhibition of a phosphatase activity as proposed for added vanadate or vanadyl ions. Alternatively the hormone action may involve stimulation of phosphorylating enzymes. Inhibition of the $(\text{Na}^+ + \text{K}^+)\text{ATPase}$ by removal of external K^+ or by ouabain or vanadate, should save cellular ATP, making more available for phosphorylation.

Vanadium is found in many cells, including classical target tissues for insulin such as skeletal muscle and liver. If, as seems likely, it is mainly in the vanadyl form and at physiological concentrations of 0.1–1.0 μM , it is available for interaction with cellular phosphatases, it could play an important part in controlling protein phosphorylation *in vivo*. An attractive possibility is that insulin bound to the cell exterior alters either the ratio of vanadyl to vanadate concentrations, or binding of the VO^{2+} ion to cytoplasmic proteins, that is VO^{2+} could be a second messenger. Possible functions of internal vanadyl ions are being investigated.

As far as we are aware this work represents the first demonstration of an effect by vanadyl ions on an important physiological process in whole cells. Whether this finding has wider implications for regulation of cytoplasmic and membrane processes by vanadyl ions remains to be established.

A site for the potentiation of GABA-mediated responses by benzodiazepines

M. A. Simmonds

Department of Pharmacology, The School of Pharmacy,
29/39 Brunswick Square, London WC1N 1AX, UK

The benzodiazepines have been well characterised as minor tranquillizers and attempts to explain their unique spectrum of activity have included suggestions that they may interact with a variety of neurotransmitter systems¹. Recently, a possible interaction with the γ -aminobutyric acid (GABA) system has received most attention. Benzodiazepines potentiate the actions of both synaptically released and exogenously administered GABA^{2–4} on mammalian neuronal preparations but the site of action within the GABA response mechanism has not been determined. Binding studies suggest that benzodiazepines combine with highly specific sites in the neuronal membrane⁵ and that these sites have some indirect association with GABA receptors^{6–11}. To investigate this association further in a functioning GABA system, quantitative studies have been made *in vitro* on neuronal depolarisations mediated by GABA receptor activation. Evidence has already been presented¹² that bicuculline is most probably a competitive antagonist at the GABA receptor while picrotoxin acts as an antagonist at a separate site. Here flurazepam is shown to attenuate preferentially the action of picrotoxin rather than bicuculline and a model is suggested for the site of action of these drugs within the GABA response mechanism.

Slices of rat cuneate nucleus were prepared as described previously¹³ and arranged in a two-compartment bath such that drugs could be superfused over the terminal regions of the afferent fibres to the nucleus and consequent changes in membrane polarisation could be recorded¹². Muscimol (Fluka) was used routinely as the agonist for GABA receptors in these quantitative studies to avoid the complications which arise when agonists such as GABA are rapidly removed by a saturable uptake process¹². Muscimol depolarised the nerve fibres in a dose-dependent manner. In the presence of 10^{-6} M flurazepam-HCl (Roche), the dose-response curve was usually shifted to the left in a parallel fashion (Fig. 1). This potentiation of muscimol was not very large but, in replicate experiments, it proved to be significant with a mean muscimol dose ratio of 0.808. At a higher concentration of flurazepam, 10^{-5} M, there was no further increase in the potentiation of muscimol and at the lower concentration of 10^{-7} M there was no significant potentiation at all.

With flurazepam still present, either (+)bicuculline (Sigma) or picrotoxin (Sigma) were added to the superfusion fluid¹² and the lower part of the muscimol dose-response curve was re-determined. Both antagonists displaced the dose-response curve to the right in a parallel fashion. For each concentration of antagonist, the equipotent muscimol dose ratio was determined and the results are presented in the form of Schild plots in Fig. 2. Control data obtained from similar experiments in the absence

of flurazepam¹² are also shown. As there was no way of determining whether bicuculline and picrotoxin antagonised the potentiating effect of flurazepam as well as antagonising muscimol, the results have been calculated in two ways: (1) assuming no antagonism of the potentiation *per se* and (2) assuming complete antagonism of the potentiation at all concentrations of antagonist. When assumption (1) was made, the potency of bicuculline as an antagonist of muscimol was not significantly reduced by flurazepam 10^{-6} M. The potency of picrotoxin, however, was consistently reduced, 2.67 times as much picrotoxin being required to achieve the same degree of antagonism as in the control experiments. When assumption (2) was made, there was an extra small reduction in the potency of both antagonists but the overall reduction in picrotoxin potency was still considerably greater than the reduction in bicuculline potency. An increase in the concentration of flurazepam to 10^{-5} M caused no further reduction in the potency of picrotoxin and flurazepam 10^{-7} M was ineffective. Other benzodiazepines must be tested to establish whether the observations with flurazepam reflect a general property of this class of drug.

Fig. 1 Depolarisations of afferent nerve fibres in a slice of rat cuneate nucleus by 2 min superfusions of muscimol. Peak responses are plotted against log muscimol concentration before (●) and during (○) the superfusion of flurazepam 10^{-6} M. Each point is a single response. The equipotent muscimol dose ratio in this experiment was 0.771. In replicate experiments, the equipotent muscimol dose ratio (mean \pm s.e.m.) in the presence of flurazepam 10^{-6} M was 0.808 ± 0.047 ($n = 24$) which is significantly less than 1 ($P < 0.01$); in the presence of flurazepam 10^{-5} M it was 0.837 ± 0.086 ($n = 12$) and in flurazepam 10^{-7} M it was 0.905 ± 0.047 ($n = 9$). In this, as in other experiments, flurazepam had little direct effect, the most usual response being a small and transient depolarisation. In control experiments, there was no sign of sensitisation or tachyphylaxis upon repeated administration of muscimol.

Interpretation of these results in terms of the site of action of flurazepam depends largely on a knowledge of the sites of action of the GABA antagonists bicuculline and picrotoxin. In the preparation used here, and in other neuronal preparations from vertebrate species, the evidence points to bicuculline being a competitive antagonist at the GABA receptor while picrotoxin acts at a different site¹². This distinction is corroborated by the demonstration of separate binding sites for bicuculline and picrotoxin^{14,15}. Penicillin appears to act as a GABA antagonist at yet another site which may be the chloride ion channel opened by the GABA receptor¹⁶. A hypothetical model of the GABA response mechanism incorporating these different sites is shown in Fig. 3.

The site of action suggested for flurazepam is based on the observation of a preferential reduction in the potency of picrotoxin rather than bicuculline and an assumption of a single site for benzodiazepine action. It seems unlikely that flurazepam and picrotoxin competed for a common site since increasing the concentration of flurazepam did not result in a further reduction

Fig. 2 Schild plots of the antagonism of muscimol by bicuculline (a) and picrotoxin (b). log (muscimol dose ratio - 1) is plotted against log (antagonist concentration) and each line was calculated by least squares regression analysis from 18-28 points. The continuous lines represent antagonist potency in the absence of flurazepam¹². The broken lines represent antagonist potency in the presence of flurazepam 10^{-6} M, the dose ratios being obtained by comparison of the muscimol dose-response curves in the presence of flurazepam and flurazepam + antagonist. The slopes of the bicuculline lines were: continuous 1.070 ± 0.032 , broken line 1.008 ± 0.070 . The slopes of the picrotoxin lines were: continuous line 0.635 ± 0.021 , broken line 0.655 ± 0.049 . Comparisons of the intercepts of the lines²⁰ at the level (muscimol dose ratio - 1) = 4 indicated: a, no significant difference between the bicuculline lines ($P < 0.1 > 0.05$) at an equipotent bicuculline concentration ratio of 1.11 b, a significant ($P < 0.001$) reduction in the potency of picrotoxin in the presence of flurazepam 10^{-6} M at an equipotent picrotoxin concentration ratio of 2.67. These comparisons of antagonist potency are based on an assumption that bicuculline and picrotoxin did not antagonise the potentiating action of flurazepam (assumption (1) in the text). Re-calculation of the muscimol dose ratios by comparing control dose-response curves with those obtained in the presence of flurazepam + antagonist (assumption (2) in the text) resulted in a small additional displacement to the right of the Schild plots obtained in the presence of flurazepam. The lines remained parallel to those obtained in the absence of flurazepam and the equipotent antagonist concentration ratios increased to 1.57 for bicuculline and 3.80 for picrotoxin.

in the potency of picrotoxin. The data from binding studies also generally indicate that benzodiazepines and picrotoxin bind to separate sites^{8-11,15} although it has recently been found that benzodiazepines can reduce the binding of dihydropicrotoxin to brain membranes¹⁷. In Fig. 3, therefore, flurazepam is suggested to potentiate an endogenous process which facilitates or prolongs the opening of the ion channel and with which picrotoxin competes. Such an action of flurazepam could account for the small potentiation of muscimol. A change in the properties of the GABA receptor⁶ appears to be a less likely explanation since the potency of the GABA receptor antagonist bicuculline was little affected by flurazepam. The model does not

Fig. 3 Hypothetical model of the GABA response mechanism and the possible sites of action of some drugs. +, Agonist or facilitatory action, including antagonism of an inhibitory influence; -, indicates antagonism. $X \rightarrow X'$ represents an endogenous process which facilitates or prolongs channel opening. The intermediate steps between receptor activation and ion channel opening seem to be the minimum necessary to accommodate the pharmacological data from depolarisation responses to GABA and muscimol of afferent nerve fibres in the rat cuneate nucleus.

allow for an enhancement of benzodiazepine binding by GABA receptor activation⁸⁻¹¹, but there is now a possibility that this effect may involve a different population of GABA receptors from those mediating changes in membrane conductance and polarisation^{18,19}.

This model has been devised as the simplest arrangement which would accommodate all the drug effects on responses to GABA receptor activation reported here and which would also be compatible with the data from binding studies. Although the stages between GABA receptor activation and ion-channel opening are entirely hypothetical, they do have possible implications. The model suggests either (i) that flurazepam increases the duration of channel opening for each GABA receptor activation or (ii) that only a proportion of the GABA receptor activations result in channel opening and that flurazepam increases that proportion. It also seems that there is no requirement for a fixed ratio of benzodiazepine sites to GABA receptors in the neuronal membrane. It remains to be seen which of these predictions are correct, but it is clear that responses to GABA receptor activation can be modulated at a number of different sites.

I thank Diana Harvey for technical assistance and the MRC for support.

Calcium transients in mammalian muscles

F. Eusebi, R. Miledi & T. Takahashi

Biophysics Department, University College London, Gower Street, London WC1E 6BT, UK

Contraction of vertebrate skeletal muscle is caused by calcium ions released from the sarcoplasmic reticulum (see refs 1, 2 for reviews). The ensuing transient change in the intracellular level of ionised calcium has been monitored using various Ca^{2+} indicators, such as murexide,³ aequorin^{4,5}, and arsenazo III^{6,7}. So far, most of what is known about these calcium transient derives from experiments on barnacle or frog muscle fibres, and it is desirable to extend such studies to mammalian muscle. We report here that the photoprotein aequorin^{8,9} can be used to monitor calcium transients in rat and human muscles, and that the transients decay more quickly in fast contracting muscle fibres.

The experiments were done on the fast-twitch extensor digitorum longus (EDL) and slow-twitch soleus (Sol) muscles of the rat, and on human intercostal muscle obtained during thoracic surgery. The isolated muscles were mounted in a bath perfused with oxygenated mammalian Ringer¹⁰, which contained $1-3 \times 10^{-7} \text{ g ml}^{-1}$ tetrodotoxin to abolish action potentials, and in most experiments 10 mM tetraethylammonium bromide was used to reduce delayed rectification. Muscle fibres were impaled

Fig. 1 Calcium transient in extensor digitorum longus (a) and (b) soleus muscle fibres of rat. The lowest traces show the aequorin responses, the middle ones record membrane potentials and the upper ones the clamp currents. Calibration bars are 2 nA for the light responses, 50 mV for the membrane potentials and 1 μA for the clamp current. Temperature, 25 °C. A time constant of 5 ms was used for the light recordings.

with two bevelled microelectrodes. One was filled with aequorin, dissolved in 120 mM KCl, 25 μM EDTA, 5 mM HEPES buffer (pH 7.9), and was used both for injecting aequorin into the fibre and for recording membrane potential. The other, inserted at a distance of 50-150 μm , was filled with either 3 M KCl or 4 M K-acetate and was used to pass current across the muscle fibre membrane to clamp the membrane potential, which was normally held at -80 mV. Aequorin was injected, under microscopic inspection by applying a pulse of pressure to the aequorin pipette. The light emitted, when Ca^{2+} combines with aequorin⁸, was recorded with a photomultiplier (EMI 9824) run at -900 V and placed about 1.5 cm above the surface of the muscle. Usually, the EDL and Sol were both mounted in the same chamber to standardise the experimental conditions.

When the muscle fibre membrane was strongly depolarised, a flash of light was recorded (Fig. 1), indicating a rise in the level of ionised calcium in the myoplasm. The Ca^{2+} is presumably released from the sarcoplasmic reticulum, since similar light responses could be recorded in Ca^{2+} -free solutions with 1 mM EGTA. Applying pulses of 20-60 ms duration, and graded intensity, to fibres held at -80 mV, light was first detected when the membrane potential was stepped to about -35 mV. This level was not very different from that at which a localised contraction in both fast and slow muscle fibres was first detected. However, in some cases the threshold depolarisation for light detection was higher than that for contraction, and the maximum light response was smaller. This probably occurred when the amount of aequorin injected by the pressure pulse was very small, or when some of the aequorin contained in the tip of the micropipette had been inactivated by the external Ca^{2+} , before insertion into the fibre. The amplitude of the light response with increasing depolarisations rose sharply at first and then tended to level off. Increasing the pulse duration increased the rise time, and amplitude of the light response. Thus, in many respects, the relationship between membrane potential and light response in mammalian muscles fibres resembles that obtained previously with arsenazo III⁶ and with aequorin (our unpublished data) in frog muscle fibres.

With depolarising pulse durations of a few milliseconds to 100 ms, the light response increased during the pulse and continued to rise well after the membrane potential had returned to the holding level (Fig. 1). A continued rise of the aequorin signal is also seen after the termination of iontophoretic pulses of Ca^{2+} discharged into droplets of aequorin¹¹. This suggests that the time during which calcium is released from the sarcoplasmic reticulum is shorter than the time to peak of the light response, and probably not much longer than the voltage clamp pulse. Presumably the depolarising pulse opens Ca^{2+} channels in the membrane of the sarcoplasmic reticulum and these channels, like those at motor nerve terminals¹², are rapidly closed once the membrane is repolarised.

The rate of rise and peak amplitude of the light response greatly depends on the amount of aequorin injected into the fibre. This makes it difficult to compare responses obtained in different muscle fibres, because it is difficult to load them always to the same degree. Nonetheless, it seems that the light response is greater in the fast EDL muscle than in the slow soleus. Preliminary examination of the relationship between membrane potential reached by the depolarising pulse, and the amplitude of the ensuing light response, indicates that the relationship is S-shaped in both fast and slow muscle fibres. The threshold for light detection is roughly the same for both types of muscles fibres, but thereafter the amplitude of the light responses to depolarising steps of increasing intensity rises more slowly, and attains a lower maximum, in the soleus fibres.

After reaching its peak, the light response decayed nearly exponentially, with a time constant that was essentially independent of the intensity and duration of the depolarising pulse. In analogy with previous results⁷ obtained in frog muscle, there was a marked difference in the rate of decay of the light responses of fast and slow muscle fibres of the rat. At 25 °C the decay time constant in EDL fibres was 16.0 ± 4.0 ms (mean \pm s.d. of 35 fibres from 14 muscles), while in Sol fibres, it was 42.4 ± 13 ms (mean \pm s.d. of 65 fibres from 13 muscles). With application of longer pulses, the light response decayed during the pulse. This decay was much slower than that after the end of a short pulse and is presumably caused by inactivation of the Ca^{2+} release mechanism from the sarcoplasmic reticulum, although other factors such as depletion of Ca^{2+} stores may be also involved. Again, the light in EDL fibres decayed more rapidly than in the soleus. The duration from half rise to half decay was 244 ± 64.6 ms (mean \pm s.d. of 8 fibres), while in Sol fibres it was 468 ± 118 ms (mean \pm s.d. of 16 fibres). The greater dispersion in the rate of decay of Ca^{2+} transients in soleus muscle fibres, may be related to the existence, in this muscle, of slow and 'intermediate' (10%) motor units¹³; but so far our results are inadequate to establish whether there are two populations of muscle fibres with clearly distinct Ca^{2+} transients. In both fast and slow muscles the light responses became slower with decreasing temperature. In the range between 15 and 40 °C, the time constant of decay changed more or less linearly with inverse temperature in Arrhenius plots in both muscles and the Q_{10} was

2.4 for EDL and 2.0 for Sol, but the difference of the Q_{10} value between EDL and Sol may not be significant considering the range of the values obtained at each temperature.

Calcium transients were also recorded from human intercostal muscle fibres; but their time course in the two samples examined so far was found to be very different. For instance, in one muscle (Fig. 2) the decay time constant of the aequorin light was 20.4 ± 3.0 ms (five fibres) while in a muscle from a different subject, it was 108 ± 22 ms (nine fibres). At present we do not know the cause of such a large difference.

The rate of rise and peak amplitude of the calcium transients in rat EDL muscle fibres was generally greater than in the soleus. This suggests that the rate of release of calcium from the sarcoplasmic reticulum may be greater in the fast fibres. Such a difference could arise from a corresponding difference in the number, or kinetic characteristics of the Ca^{2+} releasing sites in the reticulum of fast and slow fibres. The decay of the light responses reflects the time course of the processes which restore the intracellular calcium ion concentration to its resting level. It is not yet clear to what extent uptake of calcium by the sarcoplasmic reticulum is involved in determining the decay of the light responses. However, the marked difference in the rate of decay of light responses in EDL and Sol muscles is apparently in line with the observation that the sarcoplasmic reticulum is less developed^{14,15} and, when isolated, takes up calcium more slowly^{16,17} in the soleus muscle.

We thank Mr J. R. Belcher FRCS for his cooperation and Mr I. Parker for helpful discussions. T.T. is a fellow of the Wellcome Trust and F.E. was supported by a CNR-NATO fellowship.

Progressive inhibition of the Ca pump and Ca:Ca exchange in sickle red cells

Robert M. Bookchin* & Virgilio L. Lew†

* Albert Einstein College of Medicine, 1300 Morris Park Avenue, Bronx, New York 10461

† Physiological Laboratory, Downing Street, Cambridge CB2 3EG, UK

Fig. 2 Calcium transient in human intercostal muscle. Traces as Fig. 1. The calibration bar represents 2 nA for the light response, 50 mV for the potential and 1 μA for the current. Temperature, 25 °C. Time constant of light recording system, 5 ms.

Sickle cell anaemia red cells (SS) were reported to have a high Ca content and an increased Ca uptake on deoxygenation^{1,2}, but their Ca-pump activity was described as normal³. This seemed puzzling because the saturated Ca-extrusion rate of the normal, high Ca-affinity Ca pump is about 10 mmol per 1 cells per h (refs 3, 4) and the highest sickling-induced Ca influx reported in SS cells^{2,5} and observed in ATP-depleted sickle-trait (SA) red cells⁶ never exceeded 0.2 mmol per 1 cells per h. Normal pump performance is, therefore, incompatible with Ca accumulation unless SS cells have abnormally high Ca-binding capacity. We provide here evidence which suggests that SS cells have normal Ca-buffering capacity and probably genetically normal Ca pumps, but that the sickling process causes progressive Ca-pump failure and a marked reduction in Ca:Ca exchange.

Table 1 Cell-associated calcium pools in SS and normal (AA) red cells—total, ionophore mobilisable (free) and ^{45}Ca -tracer exchangeable in 2.5 h

Method	Conditions	Estimated calcium content of cells ($\mu\text{mol per 1 cells}$)	
		SS cells	AA cells
Atomic absorption spectroscopy	Washed in EGTA-free buffer	52.0 ± 8.2 (4)	11.6 ± 1.4 (3)
	Washed in EGTA-buffer	40.3 ± 17.2 (11)	5.7 ± 1.8 (7)
	After incubation with ionophore and EGTA	5.8 ± 2.3 (5)	$4.7, 5.4$ (2)
^{45}Ca influx	Washed in EGTA-buffer	4.5 ± 1.6 (5)	$1.3, 2.0$ (2)
	After incubation with ionophore and EGTA	0.26 ± 0.04 (4)	<0.20 (1)

For atomic absorption spectroscopy, red cells from fresh heparinised blood were washed four times with an ice-cold medium containing (in mM): NaCl, 140; KCl, 5; HEPES, 10 (pH 7.40); with or without EGTA, 0.1, and all buffy coat removed. Some samples were exposed to ionophore ($5 \mu\text{M}$) in the presence of EGTA at 37°C for 15 min before the final washes. After washing, the cells were lysed in distilled water, and haemoglobin precipitated with 5% trichloroacetic acid (TCA). Distilled water was deionised and gave a signal equivalent to less than $0.05 \mu\text{M}$ Ca. All the buffers used in the analysis were passed through Chelex 100 resin, TCA was redistilled following Harrison and Long¹⁵ and all plastic tubes and tips were rinsed with 5% redistilled TCA and deionised water before use. Atomic absorption spectroscopy was carried out on a Perkin-Elmer Model 360 spectrophotometer with an HGA 2100 graphite furnace, having a sensitivity of 15 pg Ca , and permitting accurate ($\pm 5\%$) measurement of $<0.5 \mu\text{M}$ Ca. Ca values (mean \pm 1 s.d.) are expressed in $\mu\text{mol l}^{-1}$ red cells, assuming a mean corpuscular haemoglobin concentration of 34 g dl^{-1} for the cells. The number of samples, each from a different patient, is shown in parentheses. Increasing the EGTA in the wash buffer from 0.1 to 5 mM did not lower the levels of red cell Ca by atomic absorption spectroscopy. The ^{45}Ca -tracer exchangeable calcium pool was estimated by measuring the influx of ^{45}Ca . Washed cells were resuspended at 10% haematocrit in the EGTA-free washing medium containing, in addition, $10 \mu\text{M}$ glucose and $1 \text{ mM } ^{45}\text{CaCl}_2$, and incubated for 2.5 h at 37°C . Subsequent washing and measurement of ^{45}Ca in the red cells were as described by Ferreira and V.L.L.⁸. The ^{45}Ca content of the cells was calculated by dividing the radioactivity per unit haemoglobin-estimated cell volume by the external specific activity of ^{45}Ca .

We first investigated the cytoplasmic Ca buffering of intact SS cells by the method of Ferreira and Lew^{3,7}. The equilibrium distribution of ^{45}Ca between cells and medium induced by a high concentration ($10 \mu\text{M}$) of the ionophore A23187 was measured with red cell suspensions (haematocrit $\sim 10\%$) from four sickle cell anaemia patients. The medium (A) contained (mM): NaCl, 75; KCl, 75; MgCl_2 , 0.2; HEPES-Na (pH 7.4), 10; glucose, 10, and two different initial concentrations of $^{45}\text{CaCl}_2$, of 0.020 and 0.100. At equilibrium, the SS cells contained 6.8–10.2 times more ^{45}Ca than equal volumes of suspension medium. The fraction of ionised Ca calculated from these values was 0.20–

0.29, falling within the lower part of the normal range (0.20–0.45)³.

It was important to determine whether the high original cell-associated Ca of the SS cells was free to equilibrate with added ^{45}Ca in the presence of the ionophore, so that the equilibrium distribution of the tracer would reflect the true distribution of the free Ca. Table 1 shows that addition of the ionophore A 23187 to EGTA-washed SS cells suspended in EGTA-containing media removed 86% of the cell-associated Ca. This indicated that most of the original cell-associated Ca was intracellular and free, and that it was available for equilibration with added ^{45}Ca in the presence of the ionophore.

There was a residual level of tightly bound, ionophore-resistant and non-exchangeable cell Ca, of about $5 \mu\text{mol per 1 cells}$, associated with both SS and normal cells. The surprising observation, however, was that in the absence of the ionophore, only about 10% of the free, ionophore-mobilisable Ca of SS cells exchanged with ^{45}Ca in 2.5 h, whereas all of the free, ionophore-mobilisable Ca of AA cells had equilibrated with the ^{45}Ca -tracer in that time. The tracer-equilibration rate of the SS cells is therefore at least 20 times slower than that observed in ATP-depleted AA cells⁸, the only conditions in which similar-size Ca pools can be maintained inside normal intact cells without ionophore or Ca-pump interference. The conclusion that Ca:Ca exchange must be extremely slow in at least some of the Ca-containing SS cells is further supported by efflux measurements from ^{45}Ca -preloaded SS cells. We see (Table 2, condition 4) a progressive reduction in the efflux of ^{45}Ca into a medium containing $1 \text{ mM } ^{40}\text{Ca}$ which, even after correcting for net ^{45}Ca release (from values in Table 2, condition 3), suggests a marked heterogeneity of exchange rates. After 2 h, the efflux of ^{45}Ca through all pathways combined had become negligibly small, whereas the cells still retained almost 22% of the initial ^{45}Ca pool. Furthermore, as there was no net Ca gain in these conditions (see Table 2, condition 3), all Ca movement across the membrane of those cells containing the residual ^{45}Ca pool, whether through pump, leak or Ca:Ca exchange, had virtually ceased.

We investigated Ca-pump function by following the release of ^{45}Ca from SS cells preincubated in the presence of $1 \text{ mM } ^{45}\text{CaCl}_2$ in the various experimental conditions described in Table 2. It can be seen (Table 2, conditions 2 and 3) that ^{45}Ca efflux is uphill, because it proceeds unchanged in the absence or presence of a large inward Ca gradient. The efflux, however, is two orders of magnitude smaller than that expected from a normal, high Ca-affinity pump saturated with internal Ca and ATP. As the ATP concentration per unit volume of cell water is apparently normal in SS cells, even in the dense cell fraction rich in irreversibly sickled cells⁹ whose Ca levels are particularly

Table 2 ^{45}Ca release from ^{45}Ca -preloaded SS cells

Condition	Pretreatment during ⁴⁵ Ca loading	Final incubation medium	⁴⁵ Ca content of cells at start of final incubation	⁴⁵ Ca efflux	Period during which flux measured (min)
			(μmol per 1 cells)	(μmol per 1 cells per h)	
1	Aerated, 90–180 min	Ca-free, 1 mM EGTA	2.9, 6.0 (2)*	0.6, 1.3	0–70
2	Deoxygenation, 90–180 min	Ca-free, 1 mM EGTA	19.2, 27.6 (2)	19.9, 20.6	0–10
3	Deoxygenation, 120 min	1 mM ⁴⁵ CaCl ₂	15.8 (1)	4.9, 5.7	10–70
4	Deoxygenation, 120 min	1 mM ⁴⁰ CaCl ₂	17.6 (1)	16.0	0–12
				3.6	12–50
				22.8	0–20
				8.7	20–40
				5.0	40–60
				2.1	60–90
				0.76	90–120

Red cells from fresh, heparinised blood were washed and resuspended (haematocrit, about 15%) in a medium similar to that used to measure cytoplasmic Ca buffering (medium A, see text) but containing $1 \text{ mM } ^{45}\text{CaCl}_2$. The cell suspensions were incubated under air (aerated) or 100% argon (deoxygenation) for the indicated times. After four washes in an ice-cold, Ca-free medium, the cells were resuspended in medium A at about 10% haematocrit and incubated at 37°C , under air, for up to 2 h. The presence in the suspension medium of EGTA, ^{40}Ca or ^{45}Ca of the same specific activity as that used during the loading period was as indicated. The ^{45}Ca content of the cells was calculated by dividing the ^{45}Ca activity per unit cell volume by the external specific activity of ^{45}Ca ; this calculation underestimates the true Ca content of the cells, because not all cell Ca had equilibrated with the tracer (see Table 1). It seems, however, a convenient way of expressing the results because it conveys some information on the approximate magnitude of the true Ca fluxes. The residual ^{45}Ca content of the cells in condition 4 after 2 h was $4.1 \mu\text{mol per 1 cells}$. Conditions 3 and 4 report the ^{45}Ca loss from the same cells in strictly comparable conditions.

* Mean values in each experiment. Number of experiments in parentheses.

Fig. 1 Effect of a deoxygenation pulse on the percentual release of ^{45}Ca from normal (AA) and sickle (SS) red cells preloaded with ^{45}Ca in the presence of the ionophore A23187. Red cells from fresh heparinised blood were washed and resuspended at about 15% haematocrit in a medium of similar composition to that used to measure cytoplasmic Ca buffering (see text) but containing 1 mM $^{45}\text{CaCl}_2$. After 90 min incubation under air (oxy) or argon (deoxy), the ionophore A23187 was added to give a final concentration of 1 μM in the cell suspension, and the incubation continued for 90 s. The cells were then washed and resuspended at an haematocrit of about 10% in the same medium. In addition, each suspension also contained EGTA, 1 mM except for the one group noted to contain $^{45}\text{CaCl}_2$, 1 mM, with the same specific activity as that used during the loading period. The residual ^{45}Ca content of the cells was measured in the TCA supernatant of the washed cell lysate⁸. Ionophore (1 μM) was added after 55 min in two of the conditions with EGTA-containing media to show that the slowly extruded Ca pool had been retained by a permeability barrier, and was not tightly bound to cell components but was free to diffuse out of the cells. Comparison of the SS (deoxy) efflux curves in the absence and presence of ^{45}Ca shows that ^{45}Ca efflux represents uphill extrusion against a steep inward Ca gradient. The small difference between the two curves represents the full magnitude of the inward Ca leaks, including any residual ionophore-mediated permeability. The contribution these leaks could have made to the observed ^{45}Ca efflux would, therefore, have been unmeasurably small. The initial ^{45}Ca content of the cells at the beginning of the final incubation and designated 100% in the curves shown was (in $\mu\text{mol per 1 cell}$): AA (deoxy), 436; SS (oxy), 187; SS (deoxy), 74.6. In a similar experiment, not shown here, the ^{45}Ca content of SS (oxy) cells fell from 51.6 to 5.8 μmol and per 1 cells in 45 min and that of SS (deoxy) cells fell from 35.1 to 12.9 μmol per 1 cells in the same period. The percentual changes were almost identical in the two experiments despite the different initial ^{45}Ca -content values.

high^{1,2}, the low Ca-extrusion rate must reflect an abnormal response of the Ca pump itself.

The nature of this Ca-pump failure was investigated by experiments similar to those described in Table 2, except that 60–90 s before the end of the preincubation the cells were more uniformly loaded with ^{45}Ca by a brief exposure to the ionophore A23187. After washing away the ionophore^{10,11}, the release of ^{45}Ca was investigated as shown in Fig. 1. We see that the ionophore allowed ^{45}Ca entry into a population of SS cells with normal Ca pumps, for the initial extrusion rate was similar in SS and normal cells. In contrast to normal red cells, however, a substantial fraction of the SS cell population exhibited weak Ca-pump activity. Furthermore, following a sickling pulse, either the fraction of weak pumping cells or the size of the Ca pool inside these cells, or both, seemed to be substantially increased.

Because some of the rapidly extruded Ca must have come from cells that had been sickled during the preincubation, a single sickling episode is not always sufficient for Ca-pump

inhibition. The mechanism of inhibition is unknown but it could involve irreversible dissociation of calmodulin from the inner pump surface, as observed with the $(\text{Mg}^{2+} + \text{Ca}^{2+})\text{ATPase}$ of SS ghosts¹². Inaccessibility of calmodulin, and even Ca, to their receptor sites on the Ca pump might result from a shielding effect by the large amount of membrane-bound, denatured haemoglobin S which has been observed in those ghosts^{13,14}.

We thank the NIH (USPHS), the MRC and the American Heart Association for funds, and Dr P. Aisen for help in using his atomic absorption spectrophotometer. R.M.B. was a Josiah Macy, Jr, Faculty Scholar.

Nitrogen-fixing growth by nonheterocystous cyanobacterium *Plectonema boryanum*

Allen C. Rogerson*

Division of Agriculture, Fort Valley State College, Fort Valley, Georgia 31030

Many oxygen-evolving nonheterocystous cyanobacteria can synthesise nitrogenase^{1,2}, but only a few are able to protect the enzyme from inhibition and denaturation by oxygen³⁻⁵. It is difficult to reconcile concomitant oxygenic photosynthesis and the obligately anaerobic process of nitrogen fixation in the remaining strains. One possibility is a temporal separation of the processes: *Plectonema boryanum* (U. Tex strain 594) has been shown⁶ to fix nitrogen and then grow oxygenically to the limits of the fixed nitrogen when incubated without combined nitrogen under N_2/CO_2 . Growth was not extensive. Here conditions are described in which the same strain of *P. boryanum* will simultaneously fix nitrogen and grow extensively, fully pigmented, apparently with sufficient metabolic energy to drive nitrogen fixation.

Preformed or exogenous carbohydrate is necessary for the expression of nitrogenase in strains such as *P. boryanum* when the enzyme is induced under N_2/CO_2 (ref. 2). Some cyanobacteria seem to prefer anoxic, reducing environments⁷, and some strains are capable of anoxygenic photosynthesis, oxidising hydrogen sulphide to sulphur⁸. *P. boryanum* is incapable of anoxygenic CO_2 fixation⁹, may be able to oxidise hydrogen sulphide to sulphur¹⁰, and will grow heterotrophically¹¹. It seemed that added carbohydrate might substitute for the lack of CO_2 fixation and that reducing conditions might inhibit oxygenic photosynthesis⁸ or chemically reduce free oxygen and thus enable nitrogen fixation and growth to occur simultaneously. Colony growth was obtained on fructose-supplemented plates

* Present address: Biology Department, St Lawrence University, Canton, New York 13617.

incubated in an anaerobic jar into which an atmosphere of 95% $N_2/5\%$ CO_2 was introduced through repeated partial evacuation, and then sulphide was added by injecting an Na_2S solution. The jar was maintained free of O_2 by a solution of sodium dithionite. Green growth required light, fructose, nitrogen gas and a limited amount of sulphide. A sulphide-stat was then constructed in which the N_2/CO_2 was first bubbled through a constantly refreshed sulphide solution so that the carry-over of sulphide into the culture medium maintained a constant sulphide concentration in the range of $5-10 \times 10^{-6}$ M. This facilitated detailed examination of nitrogenase activity and concomitant growth by the cyanobacterium.

Figure 1 shows some of the features of nitrogen-fixing growth by *P. boryanum*. After a lag of less than 1 day (some experiments had longer lags), growth proceeded logarithmically with a doubling time of about 24 h. On day 5 the culture began to lose colour, but logarithmic growth and full pigmentation were restored by the addition of fructose. The cyanobacterium would grow without a break in logarithmic growth on 0.2% fructose; Fig. 1 thus demonstrates a clear requirement for fructose. The specific activity of nitrogenase (as acetylene reduction) showed a transient peak after induction (similar to that seen following the induction of nitrogenase in *Gloeocapsa*³), reaching a specific activity of almost 5×10^{-8} M ethylene per min per mg protein, one of the highest reported for a growing cyanobacterium. Total

Fig. 1 Growth and nitrogen fixation by *P. boryanum* in the sulphide-stat. *P. boryanum* was grown under N_2/CO_2 in BG-11 (ref. 12) plus $NaNO_3$, collected and washed twice with BG-11 minus combined nitrogen, and then inoculated into the sulphide-stat. The growth vessel contained 400 ml BG-11 medium minus combined nitrogen plus 0.1% fructose buffered with $5/10^{-3}$ M N-Tris (hydroxymethyl) methyl-2-amino methane sulphonic acid, pH 7.8, and was maintained at $30^\circ C$ under 2,500-lux incident illumination. At a rate of 50 ml min^{-1} , 95% $N_2/5\%$ CO_2 was fed through a constant 500 ml of an anaerobic solution of 10^{-1} M-Tris (hydroxymethyl) amino methane, pH 7.4, 10^{-1} M sodium dithionite (which was refreshed at a rate of 4 ml h^{-1} by a similar solution containing 10^{-1} M Na_2S) and thence into the growth vessel. Strict anaerobiosis was maintained in the culture vessel and in nitrogenase determinations. Growth (x), scale units $10^{-6} \text{ g ml}^{-1}$, was monitored as protein by the Lowry *et al.*¹³ method as before¹⁴. Nitrogenase was assayed by the acetylene reduction technique¹⁵ as before¹⁴, except that the assay was performed in 10-ml plastic syringes (No. 7370, Pharmaseal Labs, Glendale), sealed with a piece of soft, translucent Teflon. Sodium dithionite (final concentration 2 mM) was added to each sample as a precaution against oxidation. Nitrogenase is expressed as relative total activity (Δ) (proportional to the ethylene evolved per min per ml), and as specific activity (\circ) (10^{-9} mol C_2H_4 per min per mg protein). Sulphide (\square), scale units 10^{-6} M, was measured using an Orion 94-161 electrode and antioxidant techniques described in Orion manual 94-161M (Orion, Inc., Cambridge, Massachusetts). The timescale (ordinate) is in days; parameters were measured at the same time each day. On day 5 de-aerated 10% fructose was injected to an additional 0.1% final concentration.

Fig. 2 Dithionite stimulation of nitrogenase activity (acetylene reduction) in cells grown in a sulphide-stat (\blacksquare , \square) and cells incubated without sulphide (\blacktriangle , \triangle). Open figures, no dithionite added to assays; closed figures, dithionite added (as in Fig. 1). Ordinate, time after addition of acetylene and dithionite. Abscissa, relative amount of ethylene evolved at the time indicated. Assayed as described in the legend to Fig. 1.

nitrogenase activity increased throughout the growth cycle. This is the first demonstration of concomitant logarithmic growth and nitrogen fixation by a blue-green bacterium lacking a cellular oxygen-protective mechanism. The sulphide concentration remained in the range of $5-8 \times 10^{-6}$ M until the end of the experiment when there was an increase. Except for the transient period between day 5 and day 7 the culture remained fully pigmented. A control culture without sulphide showed some growth, but with a much lower nitrogenase activity and with an almost complete lack of phycobiliproteins (as 625 nm absorbance). Figure 2 shows that the nitrogenase activity (acetylene reduction) in such a control culture was noticeably stimulated by added sodium dithionite, as demonstrated for similar cultures without fructose¹², whereas activity in a culture grown in a sulphide-stat was not. Thus, the sulphide-stat facilitates logarithmic, nitrogen-fixing, photoheterotrophic growth with complete pigmentation and sufficient metabolic energy to drive nitrogenase.

These observations suggest natural flexibility in the metabolism of *P. boryanum*. Presumably, carbohydrate replaces the carbon fixed through photosystem II-driven reactions and cyclic photophosphorylation generates ATP. The presence of most major pigments would suggest that photosystem II may be at least partially active.

I thank B. J. Rumph and W. J. Schubert Jr for technical assistance, H. H. Nagatani for an axenic strain of *P. boryanum*, L. Bowers and R. Cheney for reviewing the manuscript and R. Taylor for typing. Work at Fort Valley was supported by the US Department of Agriculture, SEA/CR.

Low molecular weight circular and linear DNA in mitochondria from normal and male-sterile *Zea mays* cytoplasm

Roger J. Kemble & John R. Bedbrook

Department of Cytogenetics, Plant Breeding Institute, Maris Lane, Trumpington, Cambridge CB2 2LQ, UK

Maternally inherited cytoplasmic variation in plants is well documented¹. One consequence of such variation in maize (*Zea mays* L.) is male sterility, sources of which have been classified into three groups (T, S and C) depending on nuclear gene fertility restoration²⁻⁴. These groups and the normal (N) male-fertile cytoplasm can be differentiated by restriction endonuclease analysis of mitochondrial DNA (mtDNA)^{5,6}, although differences have also been found within the N and C groups^{7,8}, and mitochondrial translation products^{9,10}. Encouraged by the finding that mitochondria of S-cytoplasmic types contain discrete small DNA species¹¹, we have looked for low molecular weight DNAs in mitochondria from plants with N, T, C and S cytoplasm. We report here that all four cytoplasm types contain supercoiled circular DNA molecules of approximately 1,940 base pairs. This is the first small supercoiled circular DNA to be found in higher plants. Its structure suggests it may be an autonomously replicated plasmid. N, C and S cytoplasm also contain a DNA species of approximately 2,350 base pairs which is not present in T cytoplasm. C cytoplasm contain two additional circular DNA species of 1,570 and 1,420 base pairs.

Figure 1 shows an electrophoretic analysis of mtDNA from the different cytoplasmic types. All bands are resistant to RNase but sensitive to DNase. There are three DNA bands which are common to all cytoplasm. These are the supercoil (CCC), open-circle (OC) and linear (L) conformations of the same sequence (Fig. 1). Evidence for such a relationship between the three bands is: (1) S₁ nuclease treatment of CCC DNA produced OC and L molecules; (2) cRNA probes¹² of OC DNA hybridised to CCC, OC and L bands of mtDNA extracts on Southern blots¹³; and (3) electron microscopy¹⁴ showed the DNA from the CCC and OC bands to consist of circular, double-stranded molecules (Fig. 2a, b). The CCC conformations of the molecules were too small for positive identification in the electron micrographs but, during purification of the CCC DNA from the preparative gel and/or the spreading technique for electron microscopy, some molecules nicked to produce OC and L forms (46% were circular) (Fig. 3c, d). Similarly, some linear molecules were formed from DNA in the OC band (40% were circular) (Fig. 3a, b). The CCC and OC bands have a similar mean length of approximately 1,940 base pairs (assuming the Φ X174 standard to be 5,380 base pairs¹⁵) (Fig. 3a, c). We conclude that this common DNA species exists, in mitochondria, as a CCC conformation which nicks to OC and L forms during mtDNA isolation.

Mitochondrial DNA of T cytoplasm plants lack the 2,350-base pair DNA species found in N cytoplasm (labelled as 'T' in Fig. 1). N and T lines from nine different nuclear backgrounds were compared and all produced the characteristic N or T pattern in Fig. 1. Mitochondrial DNA preparations from HA, RS and Q cytoplasm also had the characteristic T pattern, indicating that these cytoplasm are members of the T group^{3,4,10,16}. Six lines possessing T cytoplasm restored to male fertility by nuclear restoring genes produced the same pattern as male-sterile T types (Fig. 1, TRf track). Mitochondrial DNA was also obtained from two T seed sources which had been regenerated from callus tissue selected in the presence of *Helminthosporium maydis* race T toxin^{17,18}. The regenerated

plants were 100% male-fertile and fully resistant to the fungal toxin. However, their mtDNA produced the characteristic DNA banding pattern of T male-steriles.

S-group cytoplasm possess two linear mtDNA species not found in other cytoplasm (labelled 'S' in Fig. 1 and as described previously^{11,16,19}). S cytoplasm restored to male fertility by nuclear restoring genes show the same pattern as S male-steriles^{11,19}.

C types possess two DNA species, not found in other cytoplasm (labelled 'C' in Fig. 1). These DNA species were found in C types of the four different nuclear backgrounds examined, in RB cytoplasm which is a member of the C group^{3,4,10,16}, and in the one C cytoplasm line examined which had been restored to male fertility by nuclear restoring genes (Fig. 1, CRf track). Electron microscopic analysis¹⁴ of the C-specific DNA species showed the presence of double-stranded, circular molecules (Fig. 2c, d). The mean size of these circular molecules was about 1,570 base pairs for the slower migrating species (19% were circular) and about 1,420 base pairs for the faster migrating species (23% were circular) (Fig. 3e-h). Southern blot hybridisations¹³ showed that there is no sequence homology between the circular DNA species common to all cytoplasm described above and the DNA species specific to S or C types.

Although our data do not demonstrate a direct relationship between the presence of these low molecular weight species and male sterility, several lines of evidence suggest a specific involvement of these DNA species in such sterility. Not only is the T-type cytoplasm the only male-sterile cytoplasm to lack a DNA band when compared to N but, significantly, plants carrying T cytoplasm exhibit the most extreme expression of male sterility of all the three male-sterile cytoplasm. Plants carrying S and C cytoplasm, however, possess additional mtDNA

Fig. 1 Electrophoresis on 1.5% agarose gel of mtDNA preparations from N, T, TRf (T restored), S, C and CRf (C restored) cytoplasm in B37 nuclear background. 'm' is a marker track of bacteriophage λ DNA digested with *Hae*III, the sizes of the bands are 3.9, 2.4, 2.1, 1.7 and 1.19 kilobases. 'S', 'T' and 'C' indicate band differences pertinent to S, T and C cytoplasm respectively. CCC, OC and L indicate supercoil, open-circle, and linear bands, respectively. Etiolated shoots were grown, mitochondria purified, mtDNA isolated and electrophoresis carried out exactly as described elsewhere¹⁶. Cytoplasmic sources used were; N, T and TRf carried in A73, W59M, A495, W33, B37, B9A nuclear backgrounds. N and T were also used in CO192 \times WJ, WF9 and F7 \times F2. HA, RS and Q were in CO192 \times WJ. C was in B37, WF9, A632 and CO192 \times WJ. CRf was in B37. RB was in CO192 \times WJ. S was in W13, W117, B37, WF9, CO192 \times WJ. SRf was in B37. Eighteen members of the S group of cytoplasm were used in CO192 \times WJ.

Fig. 2 Low molecular weight circular DNA molecules from mitochondrial preparations of C cytoplasm in CO192 × WJ nuclear background. DNA bands were isolated from a preparative agarose gel. *a*, OC band (see Fig. 1); *b*, CCC band; *c*, slower migrating 'C'-specific band; *d*, faster migrating 'C'-specific band. The large circular DNA molecule in each frame is ΦX174 bacteriophage included in each spread as an internal standard.

Fig. 3 Size-frequency distribution of DNA molecules from mitochondrial preparations as in Fig. 2. *a*, Circles from OC band (see Fig. 1); *b*, linears from OC band; *c*, circles from CCC band; *d*, linears from CCC band; *e*, circles from the slower migrating 'C'-specific band; *f*, linears from the slower migrating 'C'-specific band; *g*, circles from the faster migrating 'C'-specific band; *h*, linears from the faster migrating 'C'-specific band. The size distribution of the ΦX174 molecules used as internal standards with each spread is also shown. Photographic negatives of the electron micrographs were enlarged and the length of the DNA molecules measured with a map measure.

species not found in each other or N and T types and frequently exhibit only incomplete male sterility. In fact, some S types have reverted to complete fertility in the absence of any known nuclear restoring genes²⁰.

This finding of six different kinds of low molecular weight DNA molecules in maize raises many interesting questions in addition to their role in pollen fertility. It is clearly important to investigate their origin and their mode of replication. We are now studying their sequence relationship to other DNAs of the cell. If they are self-replicating they are potentially very useful tools for the study of plant transformation.

We thank Dr R. B. Flavell for discussions, Dr P. Highton and Pamela Beattie for electron microscopy. Gifts of seeds were received from Drs B. Gengenbach, B. Forde and C. Leaver, D. Duvick and R. Kleese (Pioneer Hi-Bred), P. Peterson and R. Gunn. We also thank Dr R. Brettell for callus-regenerated Texas seed. This research was supported by fellowships from Rank Prize Funds (R.J.K.) and EMBO (J.R.B.).

A plasmid associated with virulence in the marine fish pathogen *Vibrio anguillarum* specifies an iron-sequestering system

Jorge H. Crosa

Department of Microbiology and Immunology SC-42, School of Medicine, University of Washington, Seattle, Washington 98195

Many of the high-virulence strains of the marine fish pathogen *Vibrio anguillarum* isolated from epizootics of the widespread fish disease vibriosis, harbour a specific plasmid class which is absent from low-virulence strains¹. Curing experiments have confirmed a link between this specific plasmid class and the ability of *V. anguillarum* to establish infections². In general, all bacterial virulence factors promote growth in the antagonistic environment of the host defence mechanisms. One line of defence is provided by the proteins transferrin and lactoferrin³⁻⁵, which bind iron, rendering it unavailable to pathogens. A mechanism whereby invading bacteria may successfully compete for the otherwise unavailable iron could therefore become crucial in enabling them to proliferate in body fluids and tissues. I report here evidence which shows that the *V. anguillarum* virulence plasmid specifies a very efficient iron-sequestering system enabling bacteria to survive in conditions of limited iron availability.

To determine whether a plasmid-mediated iron sequestering mechanism exists in *V. anguillarum*, the growth kinetics of selected *V. anguillarum* biotype I⁶ strains of high virulence and their cured low virulence derivatives were studied in minimal

Table 1 Correlation between presence of plasmid, ability to grow in presence of transferrin and virulence of strains of *Vibrio anguillarum*

<i>V. anguillarum</i> strain	Presence of plasmid	MM	Generation time (h) in MM+transferrin	MM+transferrin + iron	Virulence (LD ₅₀)
775(pJM1)	pJM1	1.0	1.1	1.1	1.0 × 10 ³
775 (pJM11)	pJM11	1.0	1.2	1.0	3 × 10 ³
LS173(pJM1)	pJM1	0.9	1	1.0	2 × 10 ³
133S(pJM1)	pJM1	1.1	0.8	0.9	1.3 × 10 ³
H-775-850	pJM11	1.0	0.9	1.1	0.9 × 10 ³
E-775-300	pJM11	1.1	1.0	1.0	1.5 × 10 ³
H-775-1	No plasmid	1.1	4.0	1.2	2.1 × 10 ⁷
E-775-100	No plasmid	1.0	3.5	1.0	2 × 10 ⁶
286D	No plasmid	1	2.7	1.0	1 × 10 ⁸
NCMB1291	No plasmid	0.8	2.9	1.1	2 × 10 ⁷

Clones were analysed for plasmid DNA by agarose gel electrophoresis as before⁸. pJM11 was generated by transposition of the TnA sequence containing the ampicillin resistance genes to the original *V. anguillarum* virulence plasmid pJM1 (ref. 2). Growth curves in minimal medium (MM), MM+transferrin (2.3 µM) or MM+transferrin (2.3 µM)+iron (0.2 mM FeCl₃) were obtained as described in Fig. 1. Generation times were calculated on the portion of growth curves between 6 and 14 h of growth at 22 °C. Virulence was tested on juvenile coho salmon (*Oncorhynchus kisutch*) weighing about 14 g as before¹. Virulence is quantified as LD₅₀ values (number of microorganisms that will kill 50% of the animals inoculated) as determined by the Reed-Muench method⁹.

medium in the presence of transferrin. This protein binds the trace amounts of iron present as an impurity (about 3 µM) in minimal medium, making it unavailable for bacteria growth. The strains used were the plasmid-containing, high virulence 775 (pJM11) and its isogenic low virulence derivative H-775-3 obtained by curing the pJM11 plasmid from 775 (pJM11) at 37 °C, a temperature higher than its optimal growth temperature².

Figure 1a shows that addition of transferrin (final concentration 2.3 µM) to the culture medium inhibited the growth of the low virulence plasmid-less H-775-3 strain. Addition of excess iron (as 0.2 mM FeCl₃) to the medium totally reversed the inhibitory effect of transferrin by saturation of the iron-binding sites on the protein molecule. Similar results were obtained with other cured derivatives obtained by either exposure to 37 °C (H-775-1) or to ethidium bromide (E-775-100) (Table 1). Figure 1b shows the growth kinetics for the high virulence parent strain 775 (pJM11) containing the virulence plasmid. Growth of this strain is not affected by the concentration of transferrin which is inhibitory for the cured strains. Table 1 shows that those clones which were exposed to 37 °C (H-775-850) or to ethidium bromide (E-775-300) during the curing treatments but retained the plasmid still had a high virulence phenotype. It also shows that they could grow in the presence of transferrin, indicating that the curing procedures had not modified the pathogenic properties or ability to utilise complexed iron of bacteria other than in those cured of their pJM11 plasmid. Analysis of other high and low virulence strains isolated from different locations¹ showed similar correlations between segregation of pJM11, attenuation of virulence and inability to grow in the medium with transferrin (Table 1). My results thus suggest that the *V. anguillarum* virulence plasmid specifies a very powerful iron sequestering system which enables *V. anguillarum* to utilise highly complexed iron *in vitro*.

Is the possession of this plasmid-mediated iron uptake system a selective advantage *in vivo* for *V. anguillarum* infections? The results in Table 2 strongly support this contention. In experimental infections of fish with low-virulence cured derivatives of *V. anguillarum*, the mean lethal dose values (LD₅₀) are decreased about 300-fold if iron is included in the inocula, while added iron does not affect the LD₅₀ value in infection with the plasmid-containing strain 775 (pJM11). Thus there is a greater selective advantage for the plasmid-containing strain only when iron is not included in the inoculum. These results, of course, do not preclude the existence of other chromosomal or plasmid-mediated virulence determinants, which can play a part in other stages of the invasion process. However, considering the results reported here, it is possible to speculate that breeding and selection for transferrin genotypes of salmonids which are more resistant to the *Vibrio anguillarum* plasmid-mediated iron

Fig. 1 Effect of transferrin on the growth rate of low virulence (a) and high virulence (b) *V. anguillarum*. Growth curves were obtained for: ○, minimal medium; ●, minimal medium plus 2.3 µM transferrin (Sigma); ▲, minimal medium plus 2.3 µM transferrin and 0.2 mM FeCl₃. Bacteria were grown overnight at 22 °C in a glucose-casamino acids (Difco) M9 salts minimal medium. Those cultures were used to inoculate sets of 250 ml flasks containing 100 ml of fresh similar medium at 22 °C with the different additions. Absorbance at 590 nm (*A*₅₉₀) was measured using a Gilford-vacuum micro-sample spectrophotometer. Samples were withdrawn every 2 h and the *A*₅₉₀ was determined. a, Low virulence H-775-3 strain obtained by curing plasmid pJM11 (Ap^r) from 775 (pJM11); b, high virulence *V. anguillarum* 775 (pJM11).

Table 2 Effect of iron on experimental infections of fish with cured low-virulence strains of *V. anguillarum*

Strain	LD ₅₀ control	LD ₅₀ with iron	Increase in virulence
H-775-3	2.1×10^7	8.2×10^4	256-fold
H-775-7	3.2×10^6	8.7×10^3	368-fold
E-775-100	2.1×10^6	9.0×10^3	233-fold
775 (pJM11)	4.3×10^3	3.3×10^3	1.3-fold

Control LD₅₀ values were determined as described in Table 1. LD₅₀ values with iron were determined by including 86 µg iron (as ferric ammonium citrate) in the bacterial inoculum. In all cases, inocula were injected subcutaneously (0.1 ml) behind the fish dorsal fin. No controls, into which 86 µg iron (as ferric ammonium citrate) in saline solution was injected, died.

sequestering system could open new avenues to the control of fish disease. Differences in susceptibility of salmonids with different transferrin genotypes have previously been shown in infections with the causative agent of bacterial kidney disease⁷. Experiments on this trend as well as the characterisation of the iron sequestering system in *Vibrio anguillarum* are in progress.

Williams has described¹⁰ another plasmid-mediated iron-uptake system as being specified by the Col V plasmid of those invasive strains of *Escherichia coli* associated with cases of bacteraemia in man and domestic animals. It would be interesting, both from an evolutionary as well as an epidemiological standpoint to assess whether the *V. anguillarum* and *E. coli* plasmid-mediated iron uptake systems are related.

I thank Ms Linda Luttrupp Hodges for technical assistance and Dr R. Gould for facilities and fish at the National Fisheries Research Center, Fish and Wildlife Service, Seattle, Washington. This project was supported by Sea Grant No. 04-7-158-44021 to J.H.C. from NOAA.

It is well known that the oxygen affinity of haemoglobin depends on the number of combined oxygen molecules¹. This cooperative effect is considered to arise from a reversible protein transition between two forms which differ in tertiary and quaternary structure². However, the various steps of the structural changes concerning the protein and the haem have not been identified. Using time-resolved spectroscopy coupled to flash photolysis, we have attempted to elucidate the influence of protein on the relaxation processes of haem in haemoglobin. We now report our first results obtained in a picosecond time-resolved resonance Raman study of haemoglobin.

Resonance Raman scattering from haemoglobin solution was induced by light pulse at 532 nm obtained by second harmonic generation from a YAG modelocked Quantel laser³. Two different temporal pulse lengths— 15×10^{-9} and 30×10^{-12} full width at half maximum (FWHM)—were used; the maximum energy delivered per pulse was 300 mJ and 40 mJ, respectively. By means of a cylindrical lens focusing⁴ (focal length = 750 mm), the laser beam was passed through an aperture (0.2 mm) to the haemoglobin sample. The cell (10×20 mm) containing the sample was put into another cuvette (30×30 mm) containing the same buffer as the sample. The laser beam arrived at normal incidence on one side of the first cell and approximately 30° to one side of the sample cell. This arrangement gives a good scattered signal at 90° from the incident beam, permitting the use of lower laser power and consequently, reducing the reflection. The residual Rayleigh scattering of the sample was reduced by placing an interference filter in front of the entrance slit of a polychromator (used in the first order) with an 1,800 grooves mm⁻¹ holographic grating. The detection system was similar to that used by Bridoux and Delhay⁵. The photocathode of a front stage image intensifier tube (EMI 9912) was located in the focal plane of the spectrograph. This system can give a light gain of 10^6 at the maximum photocathode sensitivity. We have chosen a gain of 10^5 . The picture on the target outlet of the intensifier tube was taken up by a vidicon SEC camera (EMR). The spatial resolution of the system was 5 lines mm⁻¹, with a sensitivity equivalent to $ASA \times 10^8$. The spectral information was obtained in a multi-channel analyser system (Didac 800) and recorded in an X-Y plotter. In all cases, to eliminate back-lash effects in the grating, the spectrometer was calibrated using the 586.0, 583.4, 580.3 and 573.9 nm lines of an argon lamp. For the recording of the spectra the input slit was set at 0.2 mm, corresponding to a theoretical spectral resolution (FWHM) of 4 cm⁻¹. The technical arrangement is shown in Fig. 1.

Haemolysates were extracted from fresh human adult blood, and membrane-free samples were obtained by centrifugation at 18,000 r.p.m. (ref. 6). Haemoglobin A was stripped of ions on a mixed-bed ion-exchange resin AG501 × 8 (Biorad)⁷. The oxygenated haemoglobin solution was buffered in 0.1 M potassium phosphate at pH 7. Deoxyhaemoglobin (Hb) was obtained by addition of a small fraction of sodium dithionite into buffered oxygenated haemoglobin (HbO₂). At room temperature Hb was converted to the carbon monoxide complex (HbCO) by using CO gas at a pressure of 1 atm above the solution. During the experiments the temperature was held at 22 °C. All solutions for the laser runs were at a concentration of 3×10^{-3} M calculated on the basis of haem. As the optical density of the sample is very high ($A_{1\text{cm},532} = 35$), the weak peak intensity (6 GW cm⁻²) used from the picosecond flash laser cannot initiate stimulated processes in the haemoglobin solution. Nevertheless, in the same optical geometric conditions, picosecond spectra show a background noise higher than that of nanosecond spectra. This noise may be due to energy dissipation processes of the electronically excited haem states⁸ produced by the high-power density laser of the picosecond pulse.

Nanosecond time-resolved resonance Raman spectra represent an average result of several laser shots (15–20 laser pulses). However, each picosecond time-resolved resonance Raman spectrum was obtained with the accumulation of 100 laser pulses (at least 2 s between each pulse). In these conditions, artefacts with repeated picosecond laser pulses are avoided because haemoglobin is always completely religated in less than 1 s. Not all spectra were smoothed out or normalised for intensity.

A typical transient picosecond resonance Raman spectrum of the haem structure-sensitive spectral region (1,300–1,700 cm⁻¹) of haemoglobin is shown in Fig. 2b. Both direct haem-protein interaction, which should change the porphyrin backbone symmetry, and iron electronic states variations, alter most of the stretching frequencies of C–C and C–N bonds in the porphyrin ring which are seen in the Raman spectrum range between 1,300

Fig. 1 Experimental arrangement.

and $1,700\text{ cm}^{-1}$ (refs 9–12). This spectrum seems to be the superposition of spectra of HbO_2 and stable deligated haemoglobin (Hb) (Fig. 2) and reflects the general pattern observed with nanosecond Raman spectra.

Relative amplitude changes between spectral bands have not been studied and correlated with laser energy. However, no laser pulse intensity dependence has been detected in the frequency positions of the transient picosecond haemoglobin spectra with an excitation wavelength of 532 nm, the frequencies of the observed bands were $1,586 \pm 2$ and $1,640 \pm 2\text{ cm}^{-1}$ for oxyhaemoglobin and $1,554 \pm 2\text{ cm}^{-1}$ for deoxyhaemoglobin. This result suggests that a Hb-like photoproduct was generated from HbO_2 , and that this photoproduct appeared in 30 ps.

The oxygen photo-deligation process is complete within 2.5 ps (ref. 13) and is initiated with the protein in the oxygenated structure (*R* configuration). A recent study of the photodissociation of HbCO by time-resolved absorption spectroscopy indicates that the iron–ligand linkage break leads to a readjustment of the haem in its protein pocket. This haem–protein readjustment occurs in microseconds¹⁴. The evolution to a more stable quaternary *T* state seems to take longer¹⁵. Also, changes in porphyrin structure caused by deligation and detected by picosecond time-resolved resonance Raman spectra cannot be associated with the protein constraints exerted on the haem; these include the imidazole strain and Van der Waals contacts. Thus, the recent finding that only a very short iron motion exists between oxy- and deoxyhaemoglobin¹⁶ confirms that the differences between the resonance Raman spectra of these compounds depend primarily on the iron coordination states (liganded or not).

From these results, we conclude the following. (1) The transient picosecond resonance Raman spectrum of HbO_2 is essentially due to a reorganisation of the porphyrin core through a change in the electron distribution resulting from the departure of the oxygen ligand. (2) The time required for the reorganisation in the structure of the porphyrin core is less than 30 ps. (3) The picosecond time-resolved resonance Raman spectra of haemoglobin are related to the haem structural state with the iron atom pentacoordinated in a *R* protein conformation before its return to the *T* stable position. (4) The picosecond time-resolved Raman data show that the haem structure is at most only slightly dependent on the protein conformations, and that the porphyrin backbone structure is not very flexible. This conclusion agrees with X-ray experiments¹⁷.

Up to now, using CARS¹⁸ and the nanosecond time-resolved resonance Raman technique^{19–21}, no significant transient constraints have been observed between photodissociated HbCO and stable deoxyhaemoglobin. Because the change in haem geometry is not associated with the *R* or *T* globin state, it is conceivable, however, that the non-equilibrium globin structure brings about some reorientation between the haem and the globin and slight changes in the haem electronic repartition.

These relaxation processes must be more sensitive to electronic absorption spectra than to resonance Raman spectra. Lyons *et al.* could have seen this effect in the slight spectral shift of 3 cm^{-1} between unliganded haem from stable deoxy- and photodissociated haemoglobin²¹. Unfortunately, the digital technique with our dispersion is not refined enough to obtain a precision of better than 4 cm^{-1} on the absolute frequencies, and in the present work, we cannot draw clear conclusions on the existence of this small shift.

Using conventional continuous-wave resonance Raman spectroscopy, previous workers have already observed that the porphyrin spectra are not modified by the *R* and *T* shapes of apoprotein^{22,23} and that the haem structure (liganded or not) is independent of the apoprotein nature—amino acid composition, protomere associations, chemical modification²⁴. Nevertheless, with respect to normal haemoglobin, only very slight shifts in Raman frequencies have been reported for a modified haemoglobin²⁵. As the oxygen affinity of haemoglobin depends
